(Dated: September 3, 2021)

In tissues as diverse as amphibian skin and the human airway, the cilia that propel fluid are grouped in sparsely distributed multiciliated cells (MCCs). We investigate fluid transport in this “mosaic” architecture, with emphasis on the trade-offs that may have been responsible for its evolutionary selection. Live imaging of MCCs in embryos of the frog *Xenopus laevis* shows that cilia bundles behave as active vortices that produce a flow field accurately represented by a local force applied to the fluid. A coarse-grained model that self-consistently couples bundles to the ambient flow reveals that hydrodynamic interactions between MCCs limit their rate of work so that when the system size is large compared to a single MCC, they best shear the tissue at low area coverage, a result that mirrors findings for other sparse distributions such as cell receptors and leaf stomata.

An indication of the importance of fluid mechanics in biology is the remarkable degree to which the structure of eukaryotic cilia has been conserved over the past billion years [1, 2]. These hairlike appendages provide motility to microorganisms [3, 4] but also direct fluid flow inside animals during development [5–7] and in mature physiology in areas from the reproductive system [8] to the brain [9]. The two extremes of this organisimal spectrum have a fundamental distinction. In unicellulars like *Paramecium*, cilia are uniformly and closely spaced on the cell surface [10], while in animals they are often grouped together in dense bundles on multiciliated cells (MCCs) [11] that are sparsely distributed on large epithelia, as in the trachea and kidney [12, 13]. This difference reflects the need in animal tissues to share surface area with cell types having other roles, such as mucus secretion.

The workings of cilia bundles and the significance of their sparse “mosaic” pattern for fluid transport have only begun to be investigated, primarily limited to *in vitro* or *ex vivo* studies [14–16]. Here we address the fluid mechanics of mosaic tissues using embryos of the amphibian *Xenopus laevis* in which, by analogy to human airways, cilia driven flow sweeps away mucus and trapped pathogens (Fig. 1). To date, the flow has served as a readout of cilia beating in the study of tissue patterning and cilia disorders [17–19]; here we take advantage of the geometry of *Xenopus* embryos to obtain side views of cilia bundles and quantify the flows they drive. As those cilia collectively sweep through cycles consisting of an extended “power” stroke and compact “recovery” stroke close to the surface [20], the flow within each bundle appears as an active vortex. While the flow driven by a single such vortex decays quickly with distance from the skin, a coarse-grained model shows that long range contributions of other bundles slows the decay of this *endogenous* flow and determines the shear stress at non ciliated cells. From measurements of beating changes induced by *exo*genous flows, we determine linear response coefficients describing the coupling between forces applied by bundles and the flows they generate; we find that hydrodynamic interactions between MCCs lead to maximization at low area coverage of shear at the intervening tissue. These results thereby suggest an explanation for the low area coverages observed in nature.

The epidermis of *Xenopus* has strong similarities with human mucociliary epithelia. The sparsely located MCCs whence emanate hundreds of cilia that drive a homogeneous anterior-to-posterior, A-P or head-to-tail, flow (Fig. 1) are surrounded by non-ciliated cells secreting mucus-like material [23], including “goblet cells” that cover most of the tissue, mosaically scattered small cells [24, 25] secreting serotonin vesicles that modulate the cil-

![FIG. 1. Ectoderm of embryonic *Xenopus laevis* at tailbud stages.](image-url)
FIG. 2. Flow field around multiciliated cells. (a) Lateral view of an MCC showing (dashed) path of cilia tips and applied force $\mathbf{F}$. (b) Experimental velocity field and vorticity in a plane normal to skin near several MCCs, with $z$ into fluid and $x$ along flow. (c) Near an MCC, as in (b), with direction of cilia tip motion (black arrows) on $\partial \Omega_c$. (d) Estimated flow field $u_0$ for an isolated MCC (blue arrows): Stokeslets (red arrows) are used to fit velocity near cilia tips. Lateral velocity as a function of $z$ at (e) $x,y = (0,0)$ and (f) $(\pm 40 \mu m, 0)$ in experiment (exp) and theory, with $u_0$ driven by an isolated bundle and $u_c$ by a bundle exposed to the endogenous flow $u_a$ (see also Figs. S1-S3 [28]).

Brightfield images of cilia and $0.1\%$ Tricaine to avoid twitching (without affecting cilia dynamics [19]). Embryos lie on one of their flat flanks at this stage, providing a side view of cilia bundles (Fig. 1), whose power strokes are in the A-P direction (left to right in figures) so cilia and the flows stay mostly within the focal plane.

In flow chamber experiments, embryos were perfused with a peristaltic pump while in a Warner Instruments chamber (RC-31A): a 4 mm $\times$ 37 mm channel cut into a 350 $\mu m$ thick silicon gasket sandwiched between two coverslips that keep the embryo in place by pressing against its sides. The dorsal part of the embryo was positioned closer to the chamber wall, the anterior region of interest was $> 2$ mm away, and the A-P axis parallel to the channel axis, the main direction of the perfusing flow.

Brightfield images of cilia and $0.2 - 0.5 \mu m$ tracers (mass fraction $\sim 0.01\%$) were acquired at 2000 frames/s for $\geq 1$s by a high speed camera (Photron Fastcam SA3) on an inverted microscope (Zeiss Axio Observer) with a long distance 63$\times$ objective (Zeiss LD C-Apochromat). Images were filtered by subtracting their moving average. Flow fields $\mathbf{u} = (u, v, w)$ were estimated by Particle Image Velocimetry (PIVlab) and averaged over time.

We set the stage by summarizing the important length and time scales. MCCs are spaced apart by $40 - 80 \mu m$ and uniformly distributed with average spacing $P \approx 2.6 \times 10^{-4} \mu m^{-2}$, giving an average spacing $d = \sqrt{A/P} \approx 62 \mu m$. With $\ell \sim 15 \mu m$ ($\ell = 14.52 \pm 0.21 \mu m$) the cilia length, the average cellular area $\sim 287 \pm 11 \mu m^2$ is $\sim \ell^2$, which gives a coverage fraction $\phi = (\ell/d)^2 \sim 0.07$. The cilia on MCCs beat at a frequency $f \sim 20 - 30$ Hz and during a power stroke their tips move a distance $\sim 2\ell$ [Fig. 2(a)] in half a period, reaching speeds $V_c \sim 4\ell f \sim 1$ mm/s, so the Reynolds number $\rho V_c \ell / \mu$ (with $\rho$ the density and $\mu$ the viscosity of water) is $\sim 0.01$, well in the Stokesian regime. Using the fluid speed $u_w \sim 0.5$ mm/s between vortices as typical of the periciliary region, the Péclet number $u_w \ell / D > 1$ even for small molecules.

Cilia within an MCC are not synchronized; their tips move in a tank-treading manner [28], generating vorticity $\mathbf{\omega} \parallel \mathbf{e}_y$ perpendicular to the beating plane. Each MCC is thus an active vortex, as seen in Figs. 2(b,c). The vorticity can exceed $\sim 150$ s$^{-1}$ $\sim 2V_c/\ell$, is colocalized with the cilia, and rapidly diffuses at larger $z$ as the flow becomes parallel to the skin. Above non-ciliated cells between MCCs, there is a shear flow for $z < \ell$, while further away ($z \geq d$), the discreteness of the MCCs is washed out by viscosity and the horizontal velocity $u$ is independent of $x$ and falls off slowly with $z$ [Figs. 2(e,f)].

The first step toward understanding the coupling between cilia beating and fluid flow involves quantifying the contribution of a single MCC. We introduce a boundary $\partial \Omega_c$ enclosing the volume $\Omega_c$ of the active vortex [Fig. 2(a)], and extrude it in $y \in [-10 \mu m, 10 \mu m]$, the measured size of the vortex. The Stokes equations in
the complement Ω′, are solved using an envelope approach [29, 30] in which the dynamics of the cilia tips determine the flow, noting that the flow from an isolated cilium is well-approximated in the far field as that of a point force (Stokeslet) [31]. We position N Stokeslets at s_n = (x_n, y_n, h_n) in Ω, and find their strengths F_n = (f_n.x, 0, f.n.z) by fitting the velocity on ∂Ω and a no-slip boundary at z = 0 [Fig. 2(d)]. This gives an estimate of the flow u_0 driven by a bundle in an otherwise quiescent fluid. The x-components are of interest, as they alone contribute to net AP flow. For z > 2ℓ, the component u_0 falls off for z >> h like the flow u_0(z) ≈ 3Fh^2/4πμz^3 above a single Stokeslet parallel to and a distance h above a no-slip wall [32] (Fig. S1 [28]). The data in Figs. 2(e,f) show a much weaker fall-off than z^{-3} for z > 2ℓ. This slow decay arises from the long range contribution of more distant MCCs, as we now show.

The flow u_s due to a force f_c can be approximated by its far field limit. In cylindrical coordinates (ρ, z) centered at the bundle, u_s ≈ hf_cS_{11}(ρ, z), with

\[ S_{11}(ρ, θ, z) = \frac{3}{2πμ} \frac{zρ^2 cos^2 θ}{(ρ^2 + z^2)^{3/2}}. \]  

The Stokeslet contributions can be lumped into an effective force F_c = ℓ^{-1} \sum_n h_n f.n.x, which, applied at z = ℓ, matches the far field u_s ≈ 2ℓF_cS_{11}. This also applies for an effective local moment (rotlet) Γ_c = 2ℓF_c [33].

The observed velocity u(z)e_z in the region z > d is independent of x (Fig. S2 [28]) and can be described most simply in a model of the skin as a uniform distribution of x-directed Stokeslets with area density P. Summing the contributions of all bundles up to a cutoff radius Λ that incorporates finite embryo size, we obtain

\[ u_{far}(z; Λ) = P F_c \int_0^{2π} \int_0^Λ ρ dρ dθ S_{11}(ρ, θ, z), \]

which has the scaling form \( u_{far} = VG(z/Λ) \), with

\[ G(χ) = 1 - \frac{3χ + 2χ^3}{2(1 + χ^2)^{3/2}} \]

and V = P F_c/μ. G decreases monotonically from G(0) = 1 to G(∞) = 0. For any fixed z, as the organism size Λ → ∞, χ → 0, giving a flow independent of z with speed V [34], while for any fixed lateral scale Λ, the asymptotic flow field vanishes as z/Λ → ∞. For the fitted parameters V ≈ 0.64 mm/s and Λ = 300 μm, u_{far} provides an almost perfect fit of the data in Figs. 2(e,f) for z > 2d (also Fig. S2 [28]). Direct summation of discrete Stokeslets on a lattice produces nearly identical results, validating the approximation of a continuous distribution for the far-field flow (Fig. S3 [28]). For this value of V and the observed density P, we have the far-field estimate F_c ≈ 150 pN. A slightly larger effective force F_0 ≈ 200 pN is obtained by solely fitting the velocity at the cilia tips (Fig. 2d), which is to be expected as this approach does not account for the endogenous flow u_c.e_z, to which a bundle is self-consistently exposed.

We estimate the endogeneous ambient flow u_a by subtracting from u_{far} the contribution from a single cilia bundle, taken as a distribution of radius d/2,

\[ u_a ≈ V[G(z/Λ) - G(2z/d)]. \]  

As u_c = u - u_a represents the contribution of a single bundle, we test the far-field estimate with a near-field fit of u_c in Ω′ by means of Stokeslets within Ω. Doing so for the volume (−15 < x < 15, −10 < y < 10, 0 < z < d), the superposition u_c + u_a gives an excellent fit to the data in Figs. 2(e,f) above and between bundles, with F_c ≈ 160 pN, nearly identical to the far-field estimate.

For comparison, the average lateral force generation over one cycle of beating (assuming only the power stroke contributes) can be estimated from resistive force theory [35] as f ∝ ζ_ℓ VC/ℓ ≈ 3 pN [28], where ζ = 4πμ/ln(√ε) is the transverse drag coefficient for a slender filament of aspect ratio ε (for cilia, ε ≈ 75). We infer from the estimated F_c that the effective number of cilia contributing to the Stokeslet is ∼ 53, about half the typically ∼100 cilia in an MCC, reflecting force cancellations from phase shifts between cilia.

The fact that F_c/F_0 < 1 shows that it is necessary to incorporate the response of a cilium to an ambient flow. We probed this experimentally by exposing the bundle to an exogenous shear flow γ_c.e_z in a flow chamber (Fig. 3). When γ_c = 0, the cilia tips move with velocity V_0 and drag the fluid, generating a negative shear rate γ_0 ≈ −23 s^{-1}. Pumping fluid in the same direction, the shear rate at the tips γ_c decreases linearly with the hydrodynamic load γ_c. The corresponding velocity V_c tends to increase, but at a much slower rate. The rate of work above the cilia tip envelope ∝ −γ_c.V_c thus decreases almost at the same rate as γ_c and for γ_c/Lc/V_c > 0.3 becomes negative, consistent with a dissipative bundle.

The lateral velocity u_c.e_z just above the bundle (z < 2.5ℓ) is well fitted by the linear combination u_c ≈ C_0 + γ_c.z (Fig. 3c) with u_0(F_0) the profile at γ_c = 0. Note that C ≈ F_c/F_0, as confirmed for the above calculations where u_c ≈ (F_c/F_0)u_0 for z > ℓ (Fig. S2b) [28]). The slope of F_c/F_0 versus γ_c/ℓ/V_0 in Fig. 3, would be unity if the bundle dynamics were fully preserved (V_c = V_0), and zero if the bundle’s force were constant. The measured slope 0.76±0.06 confirms the resistive behavior and allows us to parameterize the coupling of the cilia to the ambient flow by the linear relation F_c ≈ F_0 − αγ_c, with α = 0.76 F_0/V_0.

To close the loop on a self-consistent coupling of the bundles to the flow, we now replace γ_c with the endogeneous shear γ_a = ∂u_a/∂z|z=0, giving F_c ≈ F_0 − αC_0/3V/d(1 - O(d/2Λ))
for large tissues, we have $\gamma_a \approx 3F\ell/\mu d^3$, and thus

$$F(d) = \frac{F_0}{1 + \lambda (\ell/d)^3}, \quad (5)$$

where the $\lambda = 3\alpha/\ell\mu$ is the key parameter of the self-consistent theory. Using typical values ($F_0 = 160$ pN, $V_0 = 1.3$ mm/s, $\ell = 15 \mu m$), we find $\lambda \approx 18.6$.

The relation (5) can be used to address several aspects of sparse cilia distributions [28]. The force applied to the wall per bundle is $\sim \mu \gamma_a d^2 = 3F_0 a/(1 + \lambda a^3)$, with $a = \ell/d$, and has a maximum at $d_{max} = (2\lambda)^{1/3}\ell \approx 50 \mu m$ as does the contribution $FV$ of a single bundle to the rate of work. The force $F_w \approx \mu \gamma_a (d^2 - \ell^2)$ applied to the non-ciliated cells is maximal for $d \approx 54 \mu m$. Both values are in excellent agreement with those observed. Using the relation $\phi = (\ell/d)^2$ we can express the wall force as a function of the coverage fraction $\phi$,

$$\frac{F_w}{F_0} = \frac{3\phi^{1/2}(1 - \phi)}{1 + \lambda \phi^{3/2}}. \quad (6)$$

The contour plot of $F_w/F_0$ in the $\phi-\lambda$ parameter space in Fig. 4 shows that the optimum area fraction is a strongly decreasing function of $\lambda$ and can reach values far below unity for $\lambda \sim 20$, as in the present study. Extra endogenous loads $\gamma_m < 0$, as expected for internal tissues, appear as an additional contribution to the ambient flow $\gamma_a + \gamma_e$. These loads will contribute to (5) as lower values of $\lambda$, and indeed, consistently larger, yet still low coverage fractions of the airways of several animals have been estimated to be $0.4 - 0.5$ [14], qualitatively consistent with Fig. 4. We infer that the observed mosaic patterns are close to optimal in terms of the clearing force applied to non-ciliated cells.

We close with comments on connections to other systems with sparse distributions of active elements. The force applied to the outer fluid by the cilia tips on the envelope $\partial \Omega_c$ is equal and opposite to that applied to the skin, and we can simplify our results on the shearing of non-ciliated cells by reconsidering (2) as the flow of a patch of activity with given slip velocity $V$ of radius $\Lambda$. The shear stress driving the flow is $\tau_\Lambda \approx 3\mu V/2\Lambda$, which we assume constant over a bundle. Setting $\Lambda = \ell$ and integrating over a tissue with $N$ bundles we obtain $J \sim N\ell^2 \tau_\Lambda$. By contrast, if we set $\Lambda = R$, the local shear stress is $\tau_R = 3\mu V/2R$ and the force over the entire surface is $J_R \sim \pi R^2 \tau_R$. With $N = \pi R^2 \phi/\ell^2$, the ratio

$$\frac{J}{J_R} \sim \frac{R}{\ell} \phi \quad (7)$$

measures how well a distribution of non-interacting MCCs shears the surface relative to the collection. The linear scaling of (7) with $\phi$ is expected, but the large prefactor $R/\ell \sim 20$ (system size/MCC size) implies that $J/J_R$ can approach unity for area fractions as low as $\phi \sim \ell/R \sim 5\%$. The form of this result mirrors one found

FIG. 3. Response of a cilia bundle to shear flow. (a,b) Vorticity contours and velocity vectors before and during perfusion. (c) Velocities $\hat{u}_0$ and $\hat{u}_c$, exogenous shear flow $\gamma_e$, and linear combination $(F/F_0) \hat{u}_0 + \gamma_e z$ fitting $u_c$. (d) Linear fits of the variation of estimated force $F$, velocity $V_c$, and shear rate $\gamma_e = \partial u/\partial z$ measured above cilia tips, and rate of work $W \propto \gamma_e V_c$ (overlapping $\gamma_e$), normalized by values at $\gamma_e = 0$. Shaded regions are 95% confidence intervals of averages over 10 samples.

by Jeffreys [36] for the evacuation rate from sparsely distributed leaf stomata, rediscovered years later [37] in the context of ligand binding to sparse cell receptors [38].

The results presented here suggest that long range hydrodynamic interactions between multiciliated cells allow efficient peri-ciliary transport at relatively low coverage, favoring the coexistence of multiple cell types in large tissues. This is likely just one aspect of more general mechanisms that maintain efficient transport in the upsampling events marking the evolutionary transition from unicellular to larger multicellular systems.

SUPPLEMENTAL MATERIAL

This file contains additional experimental and calculation details.

Embryo Culture: *Xenopus* embryos were prepared as described previously [S1]. Briefly, mature *Xenopus laevis* males and females were obtained from Nasco [S2]. Females were injected with 50 units of pregnant mare serum gonadotropin 3 days in advance and 500 units human chorionic gonadotropin 1 day in advance in the dorsal lymph sack to induce natural ovulation. Eggs were laid in a 1× MMR buffer (5 mM HEPES pH 7.8, 100 mM NaCl, 2 mM KCl, 1 mM MgSO$_4$, 2 mM CaCl$_2$, 0.1 mM EDTA). *Xenopus* embryos were cultured at room temperature or 15°C in the 0.1× MMR until they reached stage 27/28. Experiments with embryos were performed at the late tailbud stages (stages 28-30, as describe in Faber and Nieuwkoop [S3]). Embryos were terminated humanely immediately following the experiments.

Our work with *Xenopus laevis* is covered under the Home Office Project License PPL 70/8591 and frog husbandry and all experiments were performed according to the relevant regulatory standard. All experimental procedures involving animals were carried out in accordance with the UK Animals (Scientific Procedures) Act 1986. Moreover, we only used surplus embryos for this study, to conform with the NC3Rs guidance to exploit the possibility to minimise the use of animals by sharing embryos with collaborators.

Statistics: To fit any quantity $y$ measured at a given hydrodynamic load $x$, we assume a linear relation $y = a + bx$ and find 95% confidence intervals for the averages $\bar{a}$ and $\bar{b}$ of the parameters $a_i$ and $b_i$ given by a least-square fit of the measured values $(x_{i,m}, y_{i,m})$ acquired for the $i$-th MCC. We have [S4]:

$$
\bar{a} = \frac{\sum_{i=1}^{N} a_i / \sigma^2_{a,i}}{\sum_{i=1}^{N} (1 / \sigma^2_{a,i})} \pm 2 \sigma_{\bar{a}}
$$

(S1a)

$$
\bar{b} = \frac{\sum_{i=1}^{N} b_i / \sigma^2_{b,i}}{\sum_{i=1}^{N} (1 / \sigma^2_{b,i})} \pm 2 \sigma_{\bar{b}},
$$

(S1b)

The standard errors for the mean parameters are the square roots of

$$
\sigma^2_{\bar{a}} = \frac{1}{\sum_{i=1}^{N} 1 / \sigma^2_{a,i}}
$$

(S2a)

$$
\sigma^2_{\bar{b}} = \frac{1}{\sum_{i=1}^{N} 1 / \sigma^2_{b,i}}
$$

(S2b)

while the parameter variances for the $i$-th MCC are

$$
\sigma^2_{a,i} = \frac{\sigma^2}{\Delta_i} \sum_{m=1}^{M} x^2_{i,m}
$$

(S3a)

$$
\sigma^2_{b,i} = M \frac{\sigma^2}{\Delta_i},
$$

(S3b)
The flow method: value from the other experiments. We normally imaged $M = 4$ conditions per MCC. For exceptions with $M = 2$, $s^2$ could not be computed directly from (S5) and was assumed to equal the largest value from the other experiments.

Fitting the near flow-field by the singularity method: The flow $u_c$ driven by the cilia in $\Omega_c$ is modelled as the superposition of the flows arising from local point forces (Stokeslets) $f_n$ applied at $s_n \in \Omega_c$:

$$u_c(b_i) \approx \sum_{n=1}^{N} f_n S(b_i - s_n).$$  \hspace{1cm} (S6)

The tensor $S$ is the well-known, exact solution for a Stokeslet next to a no-slip plane at $z = 0$ [S5]. The values of $f_n$ are found by fitting $u_c$ at $M$ collocation points $b_i$, with $M > 2N$ to avoid numerical instabilities [S6]. As no-slip boundary conditions $u_c = 0$ at $z = 0$ are implicitly satisfied, walls do not need to be discretized. The linear system (S6) is then simply recast in its matrix form $A f = u_b$, with the $3M \times 2N$ matrix $A = \begin{pmatrix} S_{11}(b_i, s_j) & S_{13}(b_i, s_j) \\ S_{21}(b_i, s_j) & S_{23}(b_i, s_j) \\ S_{31}(b_i, s_j) & S_{33}(b_i, s_j) \end{pmatrix}$ the $2N \times 1$ vector $f = \{ f_{1,1}, \ldots, f_{N,1}, f_{1,3}, \ldots, f_{N,3} \}$, and the $3M \times 1$ vector $u_b = \{ u_{c,1}(b_i), u_{c,2}(b_i), u_{c,3}(b_i) \}$. We then solve for $f$ using the backslash operator of Matlab.
Coarse-graining the bundle: The flow \( \mathbf{u}_c \) driven by the Stokeslet in the bundle can be coarse-grained further, with a smaller number of Stokes flow singularities, moving away from the bundle. We compare the fitted flow \( \mathbf{u}_c \), made up of \( N \) Stokeslets as discussed above, with the flow driven by the effective Stokeslet \( F_s \mathbf{e}_x \) applied at \((0,0,\ell)\), and the effective rotlet \( 2F_s \mathbf{e}_y \) applied at \((0,0,\ell/2)\). They share the same far-field, reflecting the fact it is driven by an active vortex. The flow driven by the entire bundle decays as \( 1/z^3 \), as for a single singularity, for \( z > 2\ell \) (Fig. S1).

Far Field fitting: The flow given by (2), is used to fit the PIV measurements for \( z > 2d \) (Fig. S2). The velocity \( u_{\text{far}}(z; \Lambda) \) depends linearly on \( V \), but not on \( R \). For a given value of \( R \), we find \( V \) by a linear least-squares fit of the data. We then simply repeat this linear fit for candidate values in the range \( 30 \mu m < R < 1 \mathrm{mm} \), with increment \( \Delta R = 10 \mu m \), and select the value of \( R \) that minimizes the \( L_2 \) fitting error.

Two-dimensional array of Stokeslets: Results similar to those presented in Fig. 2 for a uniform distribution of Stokeslets can be obtained by positioning Stokeslets \( F_s \mathbf{e}_x \) on a lattice with cut-off radius \( \Lambda \). Each element \( s_{ij} \) of the lattice is position at \((x_{ij} = id_{11} + jd_{12}, y_{ij} = jd_{21}, z_{ij} = \ell)\). From confocal imaging of the closest neighboring cells of the bundle in Fig. 2, we estimate \( d_{11} \approx 70 \mu m, d_{12} \approx 40.5 \mu m, d_{22} \approx 53 \mu m \).

Using the effective force \( F_s \) estimated by the near field fitting, and summing up the exact contribution of each MCC, we retrieve the slow decay rate observed in vivo [Figs. 2(e,f)] for \( \Lambda \approx 300 \mu m \) (Fig. S3). This is the same result found by fitting the far-field flow with Eq. (2).

Resistive force theory estimate of the effective force applied by a single cilium: We adopt a simplified view of the power stroke of a cilium as a straight rod that pivots around its base. Let \( s \in [0,\ell] \) be arclength along a cilium, with \( s = 0 \) at the base and \( s = \ell \) at the tip, and let \( \phi \) be the angle between the cilium and the wall. The lateral component of the RFT force density at \( s \) is \( f' \sim (s/\ell)\zeta \nu_c \sin \phi \), and the resulting far field velocity, given by Eq. (1), is proportional to \( h f' ds \) with \( h = s \sin \phi \). Accordingly, the effective force \( f_{\phi} = \ell^{-1} \int_0^\ell h(s,\phi)f'(s,\phi) ds \), matches the overall far field \( \ell f_{\phi} \tilde{S}_1 \) when applied at \( \ell \). We obtain \( f_{\phi} = \sin^2 \phi \zeta \nu_c / 3 \). Through the entire stroke, a cilium cycles through an angle \( \Delta \phi = 2\pi \), and we assume that the recovery stroke does not contribute to the force, so \( f_\phi = 0 \) for \( \pi < \theta < 2\pi \). Averaging \( f_\phi \) gives the effective force \( f = \zeta \nu_c (6\pi)^{-1} \int_0^\ell \sin^2 \phi d\phi \), which gives the expression \( f = \zeta \nu_c / 12 \) used in the main text.

Additional results from the self-consistent model: The self-consistent model in Eq. (5) can be
used to investigate several aspects of the phenomenology of cilia driven flow. The contour plots for the effective force $F$ and the limit velocity $V$ are shown in Fig. S4. $V$ has a maximum at $d = (\lambda/2)^{1/3} \ell \approx 32 \mu m$. The corresponding coverage fraction $\phi = (\lambda/2)^{-2/3} \sim 0.22$ is significantly larger than observed in vivo, confirming that the system is instead optimized for the wall force $F_w$ (Fig. 4) discussed in the main text.

Supplementary video: Movie of a cilia bundle and 0.2 $\mu$m diameter tracers, acquired at 2,000 frames/s, and shown at 30 frames/s. Some larger beads are also present to help visualize the flows.
