ABSTRACT

Decades of research on Internet congestion control (CC) has produced a plethora of algorithms that optimize for different performance objectives. Applications face the challenge of choosing the most suitable algorithm based on their needs, and it takes tremendous efforts and expertise to customize CC algorithms when new demands emerge. In this paper, we explore a basic question: can we design a single CC algorithm to satisfy different objectives?

We propose MOCC, the first multi-objective congestion control algorithm that attempts to address this challenge. The core of MOCC is a novel multi-objective reinforcement learning framework for CC that can automatically learn the correlations between different application requirements and the corresponding optimal control policies. Under this framework, MOCC further applies transfer learning to transfer the knowledge from past experience to new applications, quickly adapting itself to a new objective even if it is unforeseen. We provide both user-space and kernel-space implementation of MOCC. Real-world experiments and extensive simulations show that MOCC well supports multi-objective, competing or outperforming the best existing CC algorithms on individual objectives, and quickly adapting to new applications (e.g., 14.2× faster than prior work) without compromising old ones.

1 INTRODUCTION

Congestion control (CC) is a fundamental, enduring topic in networking research. Decades of study on this topic have produced a plethora of CC algorithms [1, 4, 5, 7, 8, 13, 14, 16, 22, 27, 28, 50, 54, 61]. These algorithms are motivated by new applications that impose different demands on network performance, as well as new technologies that change the underlying Internet infrastructure. The confluence of these two factors requires a CC algorithm to be deliberately designed to optimize for a particular performance objective.

Consequently, applications face the challenge of choosing the most suitable CC algorithm based on their needs. This choice is definitely not easy given the wide range of options, and the subtle differences between them that oftentimes require deep understanding of TCP minutiae. At the same time, whenever new applications with different demands emerge, it takes tremendous efforts and expertise to customize CC algorithms for their new requirements.

In this paper, we explore a basic question: can we design a single CC algorithm to satisfy different objectives? Traditional CC algorithms [4, 5, 7, 16, 22, 28, 54] are hand-crafted. They rely on certain assumptions about the network, and hardware packet-level events to pre-defined control rules based on human experience. Recent learning-based CC algorithms [1, 27] relieve the burden by applying deep reinforcement learning to automatically learn an optimal control policy for a given objective. Yet, satisfying different objectives requires us to maintain one copy for each algorithm (either traditional or learning-based), and pay excessive time to design or train an algorithm each time when a new application with a different objective arrives (§2).

We propose MOCC, the first multi-objective CC algorithm that attempts to address this question (§3). The core of MOCC is a novel multi-objective reinforcement learning framework for CC to automatically learn the correlations between different application requirements and their corresponding optimal control policies. MOCC explicitly incorporates the performance objective into both the state input and the dynamic reward function, and leverages a new policy neural network with a preference sub-network to correlate different objectives with optimal control policies (§4.1). This allows MOCC to effectively establish a single correlation model to support different performance objectives. Under this framework, MOCC further applies transfer learning to quickly transfer the knowledge learned from past experience to new applications, and optimizes the CC algorithm for a given objective, even if it is unforeseen.

MOCC achieves its goal by a combination of offline training (§4.2) and online adaptation (§4.3). In offline training, MOCC is trained over a set of well-distributed landmark objectives to learn the base correlations between application requirements and optimal policies. Then, whenever a new application arrives, MOCC can immediately provide a moderate policy using the offline trained model by correlating the application’s objective with the landmark objectives, even if it is unforeseen. Meanwhile, MOCC activates online adaptation to transfer the knowledge from the base correlation model to the new application. With transfer learning, MOCC can quickly converge to the optimal policy within just a few training iterations, orders of magnitude faster than training from scratch. In addition, to avoid forgetting the learned policies, we customize the loss function of MOCC online.
adaptation for both new arrival and old (sampled) applications. This enables MOCC to learn and apply optimal policies for new applications without compromising old ones.

We fully implement MOCC (§5) with a user-space implementation based on UDT [21] and a kernel-space implementation based on CCP [42]. We leverage OpenAI Gym [6] and Aurora [27] to implement the training and adaptation components, and use parallel training to reduce training time. For better portability, we encapsulate all MOCC’s functions into one library that is plug-and-play and readily deployable with any networking data paths that include, but not limited to, our user-space and kernel-space implementations.

We evaluate MOCC with extensive simulations and real-world Internet experiments (§6). We show that MOCC well supports multiple objectives, competing or outperforming the best existing CC algorithms (including both traditional ones and recent learning-based ones) on individual objectives (§6.1), and can quickly adapt to new application objective in 288 seconds, 14.2× faster than prior solution (§6.2). We further demonstrate the benefits of MOCC with three real Internet applications in §6.3, and inspect the fairness and friendliness of MOCC in §6.4. Finally, we deep-dive into various design choices of MOCC and its overhead in §6.5.

2 BACKGROUND AND MOTIVATION

2.1 Diverse Application Requirements

Internet applications have diverse performance requirements for the network, typically characterized by metrics such as throughput, latency, jitter, and packet loss rate [11, 15, 19, 29, 30, 44, 49, 53]. Throughput is the main metric for many applications, in which minimum bandwidth is required to provide good user experience, e.g., HD video requires (>34Mbps) to play high-definition video without rebuffering [11]. On the other hand, real-time interactive applications usually require low latency, e.g., autonomous driving requires low latency (<15ms) to react to immediate environment signals [12]. For some real-time applications, temporal packet loss is also important, e.g., online video/audio conferencing can only tolerate (<0.1%/1%) packet loss rate [17]. Emerging Internet applications such as augmented/virtual reality may have tight requirements on several metrics simultaneously [38].

To summarize, these application demands pose different requirements on Internet CC algorithms. Ideally, the CC algorithm should be multi-objective to support diverse application requirements simultaneously. However, as we will show subsequently (§2.2), none of existing CC solutions can do this.

2.2 In Pursuit of Multi-Objective CC
We broadly classify existing Internet CC algorithms into two main categories: hand-crafted [4, 5, 7, 16, 22, 28, 54] and learning-based [1, 13, 14, 27]. Traditional CC algorithms were designed for hard-wired packet-level events to pre-defined control rules based on human experience. The performance objective is implicitly encoded in the mapping, and in many cases, it is hard to infer what is exactly being optimized.

Existing learning-based CC can optimize for a given objective. Recent learning-based CC algorithms can address the above problem of hand-crafted heuristics by explicitly encoding the performance objectives in the reward/utility function and maximizing it through machine learning from network environments. Table 1 lists several reward/utility functions used by state-of-the-art learning-based CC algorithms. The reward function is typically expressed as a combination of metrics such as throughput, latency and loss rate. The coefficient parameters \((a, \beta, \gamma, \delta, \epsilon, b, c)\) can express the relative importance of these metrics based on application requirements explicitly. Thus, learning-based CC is able to perform well for a particular objective.

We use a simple simulation to showcase this. The setup follows that in Orca [1]. Specifically, we simulate a network in which the one-way delay is 20 ms, the bottleneck link bandwidth varies between 20–30Mbps, and the loss ratio is 0.02%. We compare two traditional CC algorithms (TCP CUBIC and Vegas) and two learning-based CC algorithms (Aurora and Orca). As shown in Figure 1(a), CUBIC and Vegas underutilize the bandwidth and do not perform well when the link bandwidth changes. In contrast, Aurora and Orca are trained by assigning high weight to throughput in the reward function. As a result, they achieve higher throughput than CUBIC and Vegas, and the throughput benefits are consistent under changing network conditions.

But, these learning-based CC cannot support multiple objectives. As listed in Table 1, the current learning-based algorithms set relative importance of throughput, latency and loss rate to realize different performance objectives. These coefficient parameters are fixed during training. Thus the trained agent can only optimize for a particular objective at a time. To show this, we reuse the above
Multi-Objective Congestion Control

simulated network setting to evaluate different CC algorithms (Aurora, PCC-Allegro, PCC-Vivace, BBR, Cubic, Vegas, Copa). For Aurora, we apply two models, one trained for throughput (Aurora-throughput) and the other trained for latency (Aurora-latency). We present throughput-delay plot for each CC in Figure 1(b). We take each individual 60-second run as one point, and then compute the $1 - \sigma$ elliptic contour of the maximum-likelihood 2D Gaussian distribution that explains the points. As shown in the figure, from right to left and bottom to top, these algorithms trace out a path from most latency-optimized to most throughput-optimized. Aurora-throughput provides higher throughput, while Aurora-latency provides lower latency. But each of them can only optimize for one particular objective. In comparison, we propose MOCC, a multi-objective CC that can support different application requirements. The ideal performance of MOCC is shown in the blue line. By dynamic adjusting the relative importance of its reward function, MOCC is expected to accommodate different objectives.

For learning-based approach, hypothetically, one can train a custom model for each performance objective. However, this is undesirable: given the diverse application requirements and with new applications emerging every year, it is hard to exhaust all performance objectives. And even if possible, one may need to install a copy of algorithm in each device and train the algorithm at real time when the performance objective changes. However, existing learn-based CC algorithms are not quick-adaptive. As an example, Figure 1(c) shows that re-training the model of Aurora [27] for a new objective takes more than one hour to converge. Besides these drawbacks, from a scientific point of view, we would like to explore whether it is possible to design a single CC algorithm to satisfy multiple objectives.

QUIC: QUIC [32] is a user-space transport protocol on top of UDP to improve the transport performance of Internet applications and to enable application-specific customizations. QUIC itself, however, is not tied to a particular CC algorithm. It only provides the mechanism to implement application-specific CC algorithms, and an application still needs to specify which CC it uses, which can be either a traditional or learning-based algorithm, to achieve its performance objective. As such, our work is orthogonal to QUIC, and more importantly, we show that we only need a single CC to satisfy different objectives.

2.3 Design Goals

We seek one single CC algorithm satisfying all the following three goals simultaneously.

- **Multi-objective**: The algorithm can support different applications with different performance objectives, and provide optimal control policies for individual applications.
- **Quick-adaptive**: The algorithm can quickly adapt to new applications with unseen requirements, without compromising performance of old applications.
- **Consistent high-performance**: The algorithm should maintain high-performance in various network conditions without any pre-assumption.

We are inspired by recent trend (notably, Aurora [27] and Orca [1]) to adopt RL for CC, which can readily achieve consistent high-performance. However, the challenge is how to simultaneously support multiple application objectives and quickly accommodate new arrival ones.

3 MULTI-OBJECTIVE LEARNING FOR CC

We formulate CC as a sequential decision-making problem under the RL framework. Consider a general RL setting where an agent interacts with an environment. At each time step $t$, the agent observes some state $s_t$, and chooses an action $a_t$. After applying the action, the state of the environment transits from $s_t$ to $s_{t+1}$ and the agent receives a reward $r_t$ in §2.1. The state transitions and rewards are stochastic and
Multi-objective CC (MOCC) that explicitly takes application requirements, each denoted by a weight vector of performance metrics, as state input, making our model aware of different objectives\(^2\) in addition to network conditions; and (2) we dynamically parameterize the reward function with the weight vector of application currently under training, which enables our model to learn the optimal policy for the corresponding objective. As a result, MOCC automatically learns the correlations between application requirements and the corresponding optimal rate control policies, thus achieving multi-objective (more details in §4.1).

We train our MOCC model through offline pre-training (§4.2) and online adaptation (§4.3). In particular, we leverage transfer learning techniques [3, 10, 33, 46, 55] to speedup offline pre-training as well as adapting to new applications in an online manner. In the offline phase, we pre-train our model with a well-distributed set of landmark weight vectors to learn the correlations between application requirements and optimal policies. This brings two important benefits to the online phase. First, for a new application, MOCC can immediately provide a reasonable policy even it is unforeseen, maintaining performance during the transition. Second, transferring from such base correlation model, MOCC is able to quickly converge to the optimal policy for the new application with just a few RL iterations, much faster than learning from scratch (e.g., 14.2× in our evaluation §6). Furthermore, to avoid forgetting the already learned policies for old applications, we modify the loss function of the online learning by optimizing for both the new arrival and sampled history applications, so that our MOCC can recall the learned policies for previous applications.

\(^2\)Similarly, researchers have adopted feature vectors to represent multi-user requirements in Video Streaming Dash Approach and achieved significantly better personalized QoE [20, 25].
To summarize, by deliberately architecting and training the model as above, our MOCC framework is able to learn, remember, and apply optimal rate control policies for multiple applications simultaneously while adapting to new ones on-the-fly. In §4 below, we will go deeper to design details.

4 DESIGN

We start by introducing the model architecture that enables MOCC to achieve the multi-objective property (§4.1). Then, we describe our offline training (§4.2) and online adaptation (§4.3) that can quickly adapt MOCC to new applications.

4.1 Model Architecture

To enable multi-objective, MOCC makes two main changes upon the standard RL-based CC: 1) incorporating a preference sub-network into the policy network, and 2) including application requirements in both state input and dynamic reward function. In this way, MOCC can establish the correlations between various application requirements and the corresponding optimal rate control policies.

States: State inputs to MOCC include both application requirements and network conditions. To express application requirements, we use weight vector \( \bar{w} = \langle w_{thr}, w_{lat}, w_{loss} \rangle \) which contains the relative weights of three main performance metrics in CC algorithm: throughput, latency, and packet loss rate. The range of each weight \( w_i \in (0,1) \) and \( \Sigma_i w_i = 1 \). For example, \(<0.8, 0.1, 0.1>\) means that the application desires high throughput, and \(<0.4, 0.5, 0.1>\) indicates the application is latency-sensitive but still needs certain throughput.

For network conditions, similar to prior work [14, 27, 50], we use statistics vector \( \bar{g}_t = \langle l_t, p_t, q_t \rangle \) to express the network status at time interval \( t \). Specifically, \( l_t \) is sending ratio, defined as packets sent by sender over packets acknowledged by receiver; \( p_t \) is latency ratio, the ratio of mean latency of the current time interval \( t \) to the minimum observed mean latency in the history; and \( q_t \) is latency gradient, the derivative of latency with respect to time. Furthermore, to capture the trends and changes of network dynamics, we use a fixed-length history of network statistics instead of the most recent one (i.e., \( \bar{g}_{t-\eta} = \langle \bar{g}_{t-\eta}, \bar{g}_{t-\eta+1}, ..., \bar{g}_t \rangle \) with length \( \eta > 0 \)) as network state input. This improves MOCC by reacting to network dynamics more appropriately [27].

Actions: Upon observing state \( s_t = (\bar{w}, \bar{g}_{t-\eta}) \), the RL agent chooses an action \( a_t \). Then the MOCC sender takes the output \( a_t \) to change its sending rate from \( x_t \) to \( x_{t+1} \) for the next time interval \( t + 1 \) as follows:

\[
x_t = \begin{cases} 
x_{t-1} + (1 + \alpha a_t) & a_t > 0 \\
x_{t-1}/(1 - \alpha a_t) & a_t < 0 
\end{cases}
\]  

\((1)\)

\(\alpha\) is a scaling factor used to dampen oscillations. Instead of discrete sending rate adjustment, we choose a continuous sending rate adjustment to improve model robustness and achieve faster convergence.

Rewards: The MOCC reward function \( r_t \) is dynamically parameterized with the weight vector \( \bar{w} \) of application under training, so that the RL agent can capture the requirement of the application. Specifically,

\[
\text{Reward} : r_t = w_{thr} \times O_{thr} + w_{lat} \times O_{lat} + w_{loss} \times O_{loss} \tag{2}
\]

in which \( O_{thr} = \frac{\text{Measured Throughput}}{\text{Link Capacity}} \), \( O_{lat} = \frac{\text{Base Link Latency}}{\text{Measured Latency}} \), and \( O_{loss} = 1 - \frac{\text{Lost Packets}}{\text{Total Packets}} \) are three performance measures on throughput, latency and packet loss rate. They are configured to positively relate to the final reward, and normalized to \([0,1]\) to ensure fairness among each other. We use measured maximum throughput and minimum delay to estimate the Link Capacity and Base Link Latency in the online phase.

Model structure: MOCC adopts the actor-critic method [51], a basic approach to train policy network in RL. The actor-critic method uses two neural networks: the actor network and the critic network (Figure 3). The actor network is used to represent the policy \( \pi_\theta \) that maps application requirements and network conditions to action distribution \( \pi_\theta(\bar{g}_{t-\eta}, \bar{w}, a_t) \rightarrow [0, 1] \), where \( \theta \) represents the adjustable model parameters. The critic network is to evaluate the results of actor network during training by the output value \( V^\pi_\theta(\bar{g}_{t-\eta}, \bar{w}) \). After training, the actor network is used as the policy network of MOCC.

To support multiple objectives, MOCC extends both the actor network and critic network with a preference sub-network (PN). PN takes the application weight vector \( \bar{w} \) as input, and performs feature transformation to concatenate...
with the network state $\hat{g}_{t,\eta}$ to feed both networks. Then, the actor network outputs a distribution of the action space for choosing the proper action.

By incorporating the PN, both the decisions made by the actor network and the evaluation given by the critic network are not only based on the network conditions, but also taking the application requirements into consideration. In other words, our MOCC model adopts neural network structure that can recognize different application requirements/preferences, and correlate them with the corresponding optimal policies. As a result, MOCC can learn and apply optimal rate control polices for multiple applications simultaneously, enabling multi-objective.

4.2 Offline Training

Our goal of offline pre-training is to learn the correlations between application requirements and optimal rate control policies, in order to make MOCC quickly adapt to new applications with high accuracy during deployment. In this section, we introduce our two-phase training strategy as well as the policy optimization algorithm.

**Two-phase training:** To train a multi-objective RL, one straightforward way is to decompose it into multiple single-objective RLs [36]. If we can enumerate all possible objectives and train each of them iteratively, the multi-objective RL can achieve the optimal Convex Converge Set. However, in our case of MOCC, there are infinite possible objectives, i.e., any weight vector that satisfies $w_{thr} + w_{lat} + w_{loss}=1, w_i \in (0,1)$. The problem becomes intractable.

To efficiently train MOCC, instead of exploring the whole objective space, we train on a subset of landmark objectives, say $\omega$, that can produce a satisfying model4. However, even a moderate $\omega$ with tens of objectives will take several days to train. To speedup, we introduce a two-phase training: bootstrapping and fast traversing. In bootstrapping phase, we build a base model by selecting just a small number of objectives to train. In our implementation, we chose 3 to bootstrap with, and our base model can take hours to converge.

Then, in the fast traversing phase, building on the base model, we accelerate the training of the remaining $\omega$-3 objectives by adopting a neighborhood-based transfer learning strategy [33]. This method is based on the observation that when two RLs have close objectives (i.e., similar weight vectors), their optimal solutions are close. Thus, when training a RL, we can speedup by leveraging the solutions of its neighboring RLs. To do this, we purposely arrange the $\omega$ objectives in a neighborhood-based way as shown in Figure 4. We train from one objective to its neighbor iteratively and traverse all the objectives in a cyclic way. Note that each time we do not train an objective until convergence but only for a few steps

4In $\S 6.5$, we deep-dive $\omega$ and find that $\omega = 36$ achieves a good performance.

![Figure 4: The objective training trajectory for fast traversing, generated by neighbourhood-based objective sorting algorithm (details in Appendix B).](image)

in order to achieve balanced improvement on all objectives. The whole training completes when the model converges on all objectives. We explain why such two-phase training achieves near-optimal solution in Appendix C. Deep-dive in $\S 6.5$ shows it effectively speedups the training by 18x.

**Policy optimization algorithm:** Among a variety of different algorithms for training RL [23, 39, 48], we adopt Proximal Policy Optimization (PPO) [48] as the policy optimization algorithm to train MOCC. It is a policy gradient method updating the model with estimated gradient to maximize the expected total reward. We chose PPO because: 1) it is the state-of-the-art approach and easy to tune; and 2) it performs particularly well on continuous control problem [48], which makes it suitable for deciding the sending rates.

Instead of directly optimizing the expected total reward, PPO optimizes on its lower bound, a surrogate objective function (The lower bound proof is given in [48] and [47]):

$$L_{\text{CLIP}}(\theta, \bar{w}) = \mathbb{E}_{g,t}[\min\{r_t(\theta), \text{clip}(r_t(\theta), 1 - \epsilon, 1 + \epsilon)\} \hat{\lambda}_t]$$

where $r_t(\theta) = \frac{\pi_{\theta}(a_t|g_{t},\eta)}{\pi_{\theta|g}(a_t|g_{t},\eta)}$ denotes the probability ratio of action $a_t$ compared to the current policy. The term $\text{clip}(r_t(\theta), 1 - \epsilon, 1 + \epsilon)$ clips the probability ratio to the range $[1 - \epsilon, 1 + \epsilon]$. $\hat{\lambda}_t$ represents the advantage of a specific action over the current policy. It is defined as the difference between empirical total reward applying the action $a_t$ and expected total reward applying policy $\pi_\theta$:

$$\hat{\lambda}(g_{t},\eta, \bar{w}, a_t) = \sum_{i} \gamma^i r_i - V_{\pi_\theta}(g_{t},\eta, \bar{w})$$

where $V_{\pi_\theta}(g_{t},\eta, \bar{w})$ is estimated by the critic network.

To encourage exploration of policy network, as suggested in past works [39], we add an entropy regularization term to the objective function $L_{\text{CLIP}}$:

$$L_{\text{CLIP}^+}(\theta, \bar{w}) = L_{\text{CLIP}}(\theta, \bar{w}) + \beta H(\pi_\theta(\cdot|g_{t},\eta, \bar{w}))$$

Multi-Objective Congestion Control

where $H(\cdot)$ is the entropy function of the probability distribution over actions at each time step. Thus action distribution with higher entropy is preferred, exploring a more diverse set of possible actions.

During offline training, for each step, MOCC’s RL agent performs the policy of actor network to generate a network trace for a short period of time. With the trace and collected empirical rewards, we update the critic network following the standard Temporal Difference method [52]. Then, the critic network provides $V^\pi(\tilde{r}(t,i), \tilde{w})$ for computing the advantage function according to Equation 4. Finally, the actor network is updated with gradients computed to maximize Equation 5. Because the surrogate objective is the lower bound of the expected total reward, optimization on it guarantees the improvement of the policy network on gained reward. As a result, model parameters are updated such that the new policy assigns higher probability to state-action pairs resulting in positive reward advantages, moving towards the optimal policy.

### 4.3 Online Adaptation

Our offline pre-trained model from §4.2 effectively correlates the application requirements with the optimal policies. This brings two key benefits to MOCC’s online adaptation. First, for a new application, MOCC can generate a moderate policy of rate control even the requirement is unforeseen, providing reasonable performance for the new application at the beginning. Second, starting from such moderate model, with transfer learning, MOCC is able to quickly converge to the optimal model for the new application with just a few RL iterations, which is much faster than learning from scratch (e.g., we see over 10 times faster in §6.2). These two benefits enable MOCC to adapt to any new applications on-the-fly.

However, there is one issue: we do not want to compromise the performance of old applications while adapting to new ones. Unlike offline training where all objectives are artificially generated and uniformly distributed, the objective distribution in real environment may have bias: some applications are very frequent, some are rare. Under such a bias, the traditional RL algorithm will overfit to those new frequent applications but gradually forget those old rare ones, which is undesirable.

To avoid this problem, MOCC uses a requirement replay learning algorithm [3]. During the online learning, MOCC stores encountered applications (weight vectors) in a long period of time. For each online training step, the model is trained on both the current objective and an old objective drawn uniformly at random from the pool of the stored applications. We define the online learning objective to be:

$$L_{\text{online}}(\theta) = \frac{1}{2} \left[ L_{\text{CLIP+}}(\theta, \tilde{w}_i) + L_{\text{CLIP+}}(\theta, \tilde{w}_j) \right]$$

where $\tilde{w}_i$ refers to the current application requirement, $\tilde{w}_j$ refers to a sampled old application requirement, and $L_{\text{CLIP+}}$ is the PPO surrogate objective function defined in Equation 5. In this way, MOCC not only learns new applications, but also recalls old applications and reinforces previously learned policies. Thus, MOCC can preserve the learned policies of old applications while adapting to new applications. Our evaluation in §6.2 confirms this property.

### 5 IMPLEMENTATION

Our implementation of MOCC mainly consists of two components: 1) offline training, and 2) online deployment.

**Offline training:** Directly training MOCC in real environment is slow considering the actual time cost in real control loops of CC with complex network dynamics [9, 27, 45]. To enable efficient training, we train MOCC in a networking simulator that faithfully mimics Internet links with various characteristics. Our simulator is based on OpenAI Gym [6] and Aurora [27], and further incorporates new design elements in §4.1–§4.2 that are essential to MOCC, such as the encapsulation of application requirements as state input and dynamic reward functions.

MOCC policy network uses a fully-connected MLP (Multi-layer perceptron) with two hidden layers of 64 and 32 units, respectively, and tanh activation function to output the mean and standard deviations of the Gaussian distribution of action. The critic network uses the same neural network structure to estimate the scalar value function. We control the entropy factor $\beta$ to decay from 1 to 0.1 over 1000 iterations, and set clipping threshold $\epsilon = 0.2$. For the learning rate, we adopt Adam [31], a famous adaptive learning rate optimization algorithm, switch consistently outperforms standard SGD method. Important training parameter settings are listed in Table 2. We implement our model architecture with TensorFlow 1.14.0. For PPO implementation, we use an open-source implementation of several reinforcement learning baselines.

To further accelerate MOCC’s exploration towards optimal solutions for massive objectives, in addition to the two-phase training introduced in §4.2, we also adopt parallel training. We implemented this architecture using Ray [40] and RLlib [34] to build the multiple parallel environments. For compatibility, we leverage Ray API to declare the neural network during both training and testing.

**Online Deployment:** After the MOCC model was offline trained in the simulator, it needs to be online deployed with the real Internet applications. For better portability, we encapsulate all MOCC’s functions into one library. Our library provides three main functions:

1. [https://github.com/hill-a/stable-baselines](https://github.com/hill-a/stable-baselines)
We evaluate MOCC with extensive simulations as well as real Internet experiments. Our key results are as follows:

- **Multi-objective (§6.1):** Compared with a series of heuristic/learning CC algorithms, MOCC demonstrates its multi-objective performance by competing or outperforming the best existing schemes in supporting 2 common objectives: high throughput and low latency applications (Figure 5), as well as a generalized 100-objective setting (Figure 6).

- **Quick-adaptation (§6.2):** Compared with the state-of-the-art RL CC algorithm Aurora [27], MOCC can adapt to a new application in 4.8 minutes, 14.2x faster than Aurora (Figure 7a). Furthermore, MOCC does not compromise old applications while adapting to the new one, whereas Aurora does, significantly (Figure 7b).

- **Real Internet applications (§6.3):** Among all the algorithms compared, MOCC is the only one that can simultaneously provide high bitrate/throughput for video streaming (Figure 8) and bulk data transfer (Figure 10), while delivering the lowest inter-packet latency for real-time communications (Figure 9).

- **Fairness and Friendliness (§6.4):** MOCC with the same weight achieves fair share (Figure 11, 12), and MOCC variants with different weights grab different bandwidth according to weight \( \omega \) (Figure 13). MOCC is friendly among its own variants (Figure 14) and achieves comparable TCP-friendliness as other CC schemes (Figure 15).

- **Deep-dive (§6.5) into MOCC from different aspects such as hyperparameter setting (Figure 16), CPU overhead (Figure 17), learning algorithm selection (Figure 18) and training speedup (Figure 19) has validated its design efficiency.

## Settings

Following §5, we use CCP to deploy our MOCC in both real Internet and Pantheon [59] emulated environment. We train MOCC with varied bandwidth, latency, queue size and loss rate to cover a wide range of network conditions following the settings of prior works [27, 59]. The key parameters used in both training and evaluation are shown in Table 3. In particular, when evaluating MOCC, we use a much wider parameter range beyond training to show the robustness of MOCC.

### Schemes compared

We compare MOCC with various CC algorithms, including both handcrafted and learning-based:

1. **Aurora [27]:** RL based CC algorithm, single-objective RL, Aurora-throughput and Aurora-latency basically use two separate models.
2. **Orca [1]:** RL based CC algorithm, single-objective RL combined with the classic CC (CUBIC) to achieve low overhead and high performance.
3. **PCC Allegro [13]:** learning-based, performs micro experiments to continuously explore and learn the target sending rate.
4. **PCC Vivace [14]:** learning-based, extends upon Allegro to achieve better performance.
5. **BBR [7]:** model-based heuristic, builds an explicit model based on available bandwidth and RTT, and uses the model to control congestion window.
6. **Copa [4]:** delay-based heuristic, computes the target sending rate by estimating minimum delay.
7. **TCP CUBIC [22]:** loss-based heuristic, when packets are dropped, CUBIC modulates its congestion window based on a CUBIC function.

Figure 5: The multi-objective performance of MOCC in terms of throughput (a-d) and latency (e-h), under various network conditions. Note that the network conditions under evaluation are far beyond the environment where MOCC was trained, demonstrating both its high performance and robustness when adopted in practice.

(8) TCP Vegas [5], delay-based heuristic, uses RTT as congestion signal and controls congestion window to maintain desired RTT.

6.1 Multi-objective Performance
To evaluate MOCC’s multi-objective performance in supporting different application requirements, we compare it against the above CC algorithms across different network conditions.

2-objective: We first consider a simple case with two common objectives: high throughput and low latency. Even so, as high throughput and low latency typically conflict with each other, it is not easy to achieve both at the same time in prior solutions (§2.2). However, we show MOCC can achieve both objectives simultaneously, with weight vectors \( w_1 = <0.8, 0.1, 0.1> \) and \( w_2 = <0.1, 0.8, 0.1> \) respectively.\(^6\)

The detailed results are shown in Figure 5: (a) to (d) show the bottleneck link utilization with varied bandwidth, one-way RTT, loss rate and buffer size when the application prefers high throughput; (e) to (h) show the latency ratio [58] when the application demands low latency.

In general, MOCC can compete or outperform the best existing CC algorithms and show consistent high performance. First, for hand-crafted CC schemes, MOCC can at least rival them in one objective and outperform them in the other, or even both. For example, MOCC achieves comparable throughput as BBR, while delivering up to 18.8% (1.12 to 1.38 in Figure 5(e)) lower latency. Furthermore, MOCC outperforms CUBIC in both throughput (at least 1.5x from 0.95 to 0.62 in Figure 5(b)) and latency (15% lower from 1.13 to 1.33 in Figure 5(e)). The reason is that handcrafted CC algorithms generally adopt hardwired policies based on pre-assumptions of network conditions and human experiences, thus hard to achieve optimal application-specific performance, not to mention multi-objective. In contrast, MOCC explicitly considers application requirements in both state input and reward function, effectively solving the problem with multi-objective RL.

Second, we find that learning-based CC algorithms (non-RL), such as PCC Vivace and PCC Allegro, which essentially use online greedy optimization method, could lead to local optimization. MOCC uses RL to avoid this problem, and thus outperforms them with up to 1.43x better throughput (0.83 to 0.58 in Figure 5(c)) and 63.2% latency reduction (1.20 to 3.27 in Figure 5(h)) respectively.

Third, compared to RL-based Aurora/Orca, we see that MOCC outperforms Aurora-throughput in terms of latency (21.6% lower from 1.16 to 1.48 in Figure 5(f)) while exceeding Aurora-latency in terms of throughput (1.3x from 0.89 to 0.66 in Figure 5(a)). Default Orca [1] shows similar trend except in the random loss case, due partially to the effect of CUBIC (its heuristic part). These results are expected because they use single-objective RL, which cannot simultaneously optimize for both throughput and latency, thus leading to degraded performance. On the contrary, MOCC uses multi-objective RL to simultaneously support both objectives with one model.

\(^6\)Note that we only used these two particular weight vectors as example, and any vectors with similar weight settings would work.
Not compromising old applications

The readers may wonder: can we pre-train a few variants of Aurora/Orca (with different weights) to achieve multi-objective?

100-objective: To answer the above question, we consider a more generalized, uniformly-distributed 100-objective setting. To make our results visually clear, we unify the performance metrics using reward calculated by Equation 2. In this experiment, MOCC only used offline trained model without online adaptation although with which we believe is even better. We enhanced Aurora with 10 pre-trained models that best suit these 100 objectives (Orca shares similar property in terms of single-objective RL).

We run MOCC, enhanced-Aurora, and other CC algorithms under 10 different network conditions with 100 objectives, resulting in 1000 different scenarios. Figure 6 presents CDFs of rewards of these 1000 cases for all the algorithms compared. It is evident that MOCC outperforms all other CC schemes (including enhanced-Aurora) in satisfying various objectives across different network conditions. We find that enhanced-Aurora with 10 pre-trained models is secondary to MOCC, but vanilla Aurora with single model cannot perform well. The handcrafted heuristics, as expected, cannot well meet the multi-objective requirements because they are designed with no explicit application requirements in mind and their control policies are hardwired with pre-assumptions.

6.2 Quick Adaptation

To show how quickly MOCC adapts to new applications, we compare it against Aurora. We define the convergence point as 99% of the maximum reward gain.

Figure 7(a) plots the trend of both algorithms in adapting to new applications. The x-axis denotes the number of iterations and y-axis the gained reward. First, we observe that MOCC achieves 1.8× higher initial performance for a new application over Aurora. This suggests that by learning correlations between application requirements and optimal policies, MOCC can provide moderately good policies for applications with unseen requirements. Meanwhile, with transfer learning, such base correlation knowledge brings a 14.2× faster convergence speed (639 down to 45 iterations). This result confirms that MOCC can quickly adapt to new applications, whereas the single-objective Aurora, without the correlation knowledge, re-trains the model from scratch which takes long time.

Figure 7(b) checks whether MOCC will degrade the performance of old applications while adapting to new ones. To do so, we snapshot the models of MOCC and Aurora every 8 iterations, and apply them to the old application to compute the rewards. The curves are illustrative. We observe that MOCC well preserves the performance of the old application with reward loss <5%. This is because MOCC has the correlation model and applies the requirement replay algorithm (§4.3) to recall the old application during online training. In contrast, Aurora, as a single-objective CC model, gradually forget the old application and degrades the performance greatly (916.1 to 156.1) while serving the new application.

6.3 Real Internet Applications

We now showcase the performance of MOCC with 3 real Internet applications: video streaming, real-time communications (RTC), and bulk data transfer. These applications have different requirements, and we use a single MOCC model to support all of them. We use CCP to deploy our MOCC on Linux kernel 4.15.0-74-generic. We compare it with TCP CUBIC, Vegas and BBR which are built-in algorithms in Linux Kernel and widely used in Internet.

Video streaming: In this experiment, we deployed a video streaming server and use ABR algorithm provided by Pensieve [45]. We applied \( \hat{w} = <0.8, 0.1, 0.1> \) for MOCC because video streaming applications need high throughput and are not sensitive to latency due to the playback buffer. We used our browser on client to play the video from the server via both WiFi and wired networks.

The experimental results are shown in Figure 8. We can see that MOCC continuously outperforms other CC algorithms.
in terms of throughput Figure 8 (top). Specifically, the average throughput of MOCC is 91.3% (4.4 to 2.3 Mbps) higher than Vegas, 33.3% (4.4 to 3.3 Mbps) higher than CUBIC, 29.4% (4.4 to 3.4 Mbps) higher than BBR. Figure 8 (bottom) shows the number of chunks with different quality levels (higher is better, level 5 is the best) obtained during video streaming. The level of chunk obtained is decided by MPC algorithm and a better networking condition leads to a higher level of chunks. In our experiment, MOCC can obtain the largest number of level 5 chunks compared to others (14 in MOCC vs 9 in BBR, 2 in CUBIC, and 0 in Vegas). The result further shows that MOCC can satisfy the requirement of video streaming application, outperforming the other algorithms.

Real-time communications (RTC): We deployed Salsify (the latest real-time WebRTC) [18] for RTC application. We modified Salsify to work with TCP. We applied $\bar{w} = <0.4, 0.5, 0.1>$ for MOCC because besides throughput, RTC applications also care about latency to avoid lags. We used our browser on client side to set up a conference call with the Salsify server via both WiFi and wired networks.

Figure 9 shows the average inter-packet delay. We observe that MOCC achieves the lowest inter-packet delay and is 21.1% (3.0 to 3.8 ms) better than BBR, 63.1% (3.0 to 7.9 ms) than CUBIC and 26.8% (3.0 to 4.1 ms) than Vegas. The result suggests MOCC can deliver the best performance to RTC applications by keeping low inter-packet delay.

Bulk data transfer: For bulk data transfer, we connected a server and a client by a switch and sent large file via Python.
As the file transfer is throughput-hungry, we greedily applied \( \hat{w} = \langle 1, 0, 0 \rangle \) for MOCC. We transfer a 100MB file for 50 times. We also add a random loss rate of 0.5\% to the links to emulate background traffic interference.

Figure 10 shows the results. Compared to others, MOCC achieves the lowest average file transfer completion time and is 1.56\% (8.83 to 8.97 ms) than CUBIC, 1.78\% (8.83 to 8.99 ms) lower than BBR and 7.63\% (8.83 to 9.56 ms) than Vegas. Besides, MOCC maintains the most stable performance, and the standard deviation of these 50 measurements is 0.096, while BBR is 0.154, CUBIC 0.123 and Vegas 0.421, respectively. This result shows that MOCC can provide consistent high bandwidth to throughput-intensive applications.

### 6.4 Fairness and Friendliness

To evaluate the fairness and friendliness of MOCC, we compare MOCC with other CC schemes using Pantheon [59]. Fairness considers the scenarios where all flows use the same CC scheme, and friendliness considers those with different CC schemes (including MOCC with different weights).

**Fairness:** We use a canonical setting for evaluating fairness: several flows use the same CC scheme to share a bottleneck link in a dumbbell topology. The link is configured with 12Mbps bandwidth, 20ms RTT and 1 × BDP buffer, and three flows initiates sequentially with a 100s interval. Figure 11 shows the throughput of different flows for each scheme. As expected, MOCC (with the same weight) allocates bandwidth fairly between competing flows. Furthermore, it also achieves fast convergence, because it adjusts the sending rate with a multiplicative factor as defined in Equation 1.

We also use the Jain’s fairness index [26] to quantitatively compare the fairness of different schemes for the same setup. A close-to-1 value indicates better fairness. We compute the Jain’s fairness index for each second for each scheme, and compare the fairness of different schemes for the same setup. The results indicate that MOCC can provide consistent high bandwidth to throughput-intensive applications.

**Friendliness:** We first evaluate the friendliness of MOCC with different weights. The setup has two flows sharing a bottleneck link of 20Mbps bandwidth, 20ms RTT and 1 × BDP buffer. We use three MOCC variants, which are MOCC-Throughput, MOCC-Balance, and MOCC-Latency. Figure 13(a)(b)(c) show pairwise competitions of the three variants. These MOCC variants are technically different CC schemes, and a variant with a larger weight \( \omega \) would be more aggressive to get more bandwidth. For comparison, Figure 13(d) shows the result for a TCP Cubic flow vs. a TCP Vegas flow.

MOCC is friendly in the sense that no MOCC flow will grab all bandwidth when multiple MOCC flows with different weights co-exist. This is because all MOCC flows share one objective framework, which is guaranteed to converge to a stable rate configuration [24]. We performed another simulation to further demonstrate this point with more MOCC variants in Figure 14. We fix the bandwidth to 20Mbps and change the RTT from 10ms–90ms. The results show that the throughput ratio varies between 0.43–2.04, which confirms the friendliness of MOCC under different weights.

Finally, we evaluate the friendliness of MOCC with other TCP schemes. We use a common setup that has two flows competing one link. Following the convention of friendliness evaluation in prior work [1, 14], we fix TCP Cubic as the target CC scheme of one flow, and vary the CC scheme of the other flow to compare between them. We use the friendliness ratio as the metric, which is defined by \( \frac{Delivery-rate-of-CC-scheme}{Delivery-rate-of-Cubic-flow} \). Figure 15 reports the friendliness ratios of different schemes. The results indicate that MOCC-Throughput is more aggressive in obtaining bandwidth, and MOCC-Balance and MOCC-Latency are more friendly to TCP Cubic. In general, MOCC is comparable to other CC schemes in friendliness.

### 6.5 MOCC Deep Dive

Finally, we deep-dive into MOCC from some other aspects, including hyperparameter setting, CPU overhead, learning algorithm selection, and training speedup.

**Hyperparameter setting:** We explore several key hyperparameters that may affect the effectiveness of MOCC, i.e., the learning-related parameters in Table 2. For history length (\( \eta \)) and discount factor (\( \gamma \)), we performed an exhaustive search and obtain similar results with [27]. For learning rate \( \epsilon \), we followed the default value suggested in stable-baseline’s PPO [48], and we also tried several different values and found that \( \epsilon = 0.001 \) indeed leads to fast convergence. For the remaining, we discuss the number of pre-grained objective weight vectors (\( \omega \)) that is unique to MOCC.

![Figure 16: Hyperparameter setting (\( \omega \))]
We use taskset to allocate processes to one CPU and report CPU utilization by `htop`. We exclude the first and the last few seconds for fair comparison. Results in Figure 17 show that User-space MOCC has high overhead similar to Aurora, because MOCC agent repeats model inference in each time interval similar to Aurora. Kernel-space MOCC achieves much lower overhead as Orca [1], because with CCP, the algorithm logic is isolated from the datapath. This decoupling provides CC feedback less frequently and significantly reduces the CPU utilization.

Learning algorithm selection: In this paper, we chose the PPO algorithm as our RL algorithm. An alternative approach is Q-learning [52]. In this experiment, we compare both algorithms to revisit the design decision of using PPO. For this purpose, we implemented a Q-learning version of MOCC, MOCC-DQN. Figure 18 compares MOCC-PPO with MOCC-DQN. We observe that MOCC-PPO significantly outperforms MOCC-DQN by achieving 3× more rewards on average. The reason is that for CC problems, the sending rate is a continuous value. However, Q-learning scales poorly with the continuous action space, causing sub-optimal performance. On the contrary, PPO is able to output continuous action values. So we select PPO to enable a more fine-grained rate control policy.

Training speedup: We evaluate the effectiveness of our training speedup techniques, including both neighborhood-based transfer learning strategy and parallel training. We train MOCC in three ways. First, we treat each single-objective as a standard RL subproblem and train them separately. Second, we use two-phase training with neighbourhood-transfer method (§4.2), without parallel training. Third, based on the second one, we add parallel training. The results are shown in Figure 19. We observe that through transferring across neighbor objectives, we reduce the training time by 18× (6 days 7.2 hours to 8.4 hours), which validates that transfer learning can significantly accelerate the training. In addition, we find parallel training can further speedup the training by 4× (8.4 to 2.1 hours).

7 DISCUSSION & FUTURE DIRECTIONS

Expressing application requirements: In MOCC, an application expresses its requirement as a weight vector over several network-level metrics (e.g., throughput, latency and packet loss rate), and MOCC trains a model to optimize for the vector. Yet, applications care about application-level objectives, which may not be directly mapped to a weight vector of network-level metrics. At a high level, the weights...
should be set based on the application-level objectives, e.g., real-time applications should give a higher weight to latency, and bandwidth-intensive applications should give a higher weight to throughput. But how to optimally set the weights to best express an application’s requirement still requires human expertise and domain knowledge. We envision a learning-based approach, which learns the mapping from an application-level objective to a weight vector, can be applied to automate this process and reduce human efforts.

**Model sharing and Federated learning:** For an unseen application, MOCC leverages transfer learning to quickly adapt its model to the new application. Another device may have already run this application and trained a model to optimize the performance. If different devices can share their models, it would further reduce the adaptation time for MOCC. However, sharing models may raise privacy concerns as a trained model may unexpectedly leak a user’s traffic pattern and network condition, which could be further used to reveal the user’s other sensitive information. This setup is similar to federated learning where a model is trained across multiple decentralized devices. Extending MOCC with privacy-preserving federated learning is an interesting future direction.

**Towards a general multi-objective framework for networking:** While we focus on congestion control in this paper, we believe the framework behind MOCC is more generic and can be applied to a wide range of networking problems [9, 35, 45, 56]. This framework is particularly relevant to the recent proposals that leverage reinforcement learning to solve networking problems and demonstrate superior performance over traditional heuristics. For example, it can be applied to NeuroCuts [35] to learn to build packet classification trees with multiple objectives on classification time and memory footprint, and be applied to Pensieve [45] to learn adaptive bitrate algorithms with different Quality of Experience (QoE) metrics.

**REFERENCES**

Multi-Objective Congestion Control

We use multiple-policy approach to optimize for each application preference rather than average preference of all applications. Existing MORL algorithms can be divided into two groups: single-policy approaches and multiple-policy approaches [37]. While single-policy approaches learn a single policy to optimize the average performance among different objectives, multiple-policy approaches learn and maintain a set of optimal policies. A general method adopted by multiple-policy approaches is to collect policies by running standard RL algorithm over different preferences [43]. To simultaneously support multiple existing applications and quickly adapt to new arrival applications while not compromise the performance of old applications, MOCC adopts multiple-policy approach to learn and maintain multiple policies for every application requirement.

We use policy-based rather than value-based algorithms to optimize for CC where the decision space is continuous instead of discrete. The training approach for RL can be divided into two groups: value-based approaches and policy-based approaches. Value-based approaches estimate the value of each state, and take action with highest value estimation. Policy-based approaches directly learn the optimal policy for the task. Generally, policy-based algorithms outperform value-based ones for continuous control problems because policy models can directly output continuous action [48]. Recent MORL algorithms are all value-based approaches [2, 46, 60]. However, to better fit the continuous property of the sending rate in CC, MOCC adopts policy-based algorithm PPO and transfers MORL structures from value-based to policy-based.

Besides, based on the above design choices, we also make following two enhancements towards MORL:

Enhance PPO with requirement replay learning algorithm in order not to compromise performance of old application. DQN-based Conditional Network (CN) proposed in [2] adopts new training policy to adapt to new policy as well as maintain previously learned policies. Based on it, we design the requirement replay learning mechanism for PPO during online learning (§4.3) to recall old applications.

Enhance MORL training with transfer learning to accelerate training speed. Furthermore, with the prospect shown in [46] of using transfer learning to solve new objective faster from similar learned objectives, we design the two-phase offline training scheme with the neighbourhood-based algorithm (§4.2) to unleash the full power of transfer learning and significantly speedup our training (§6.5).

B NEIGHBORHOOD-BASED ALGORITHM

In the fast traversing phase of offline training (§4.2), to speedup the training speed, we design a neighborhood-based algorithm to leverage the solutions of its neighboring RLs.
Our algorithm is based on Dijkstra’s shortest path algorithm. By constructing an undirected graph $G$ from candidate objectives, we reorder objectives according to their distances from the bootstrapped ones. We construct $G$ with vertices representing candidate weight vectors (all weight vectors satisfying $w_{thr} + w_{lat} + w_{loss}=1$, $w_i \in (0,1)$, at a given step size), and edges representing the neighborhood relationships. We define two weight vectors to be neighbor if they have difference in at most two dimensions and the difference is within unit step size. For example, at the step size of 0.1, $<0.2,0.4,0.4>$ and $<0.2,0.5,0.3>$ are neighbors, $<0.2,0.4,0.4>$ and $<0.1,0.5,0.4>$ are neighbors, but $<0.2,0.4,0.4>$ and $<0.1,0.3,0.6>$ are not neighbors. We add edges between neighbors and set all edge weights to be 1.

Algorithm 1 presents the pseudocode for our neighborhood-based algorithm on $G$. We iterate on each bootstrapped objective/vertex and apply Dijkstra’s algorithm: For the current bootstrapped vertices $o$, the algorithm extracts the nearest unvisited vertices, puts it into the list $L$, and updates its unvisited neighbors’ distances from $o$. Finally, $L$ contains a sorted list of objectives that can be used as the training order for our MOCC model.

To accelerate the fast traversing phase, we chose the bootstrapped objectives $<0.6,0.3,0.1>$, $<0.1,0.6,0.3>$, $<0.3,0.1,0.6>$ to cover different application requirements as much as possible. Figure 4 illustrates the traversing path.

**Algorithm 1: Neighborhood-based Objective Sorting Algorithm**

```
input : The undirected objective graph $G = (V,E)$, the bootstrapped vertices $O$
output : The sorted objective list $L$

1. $L \leftarrow []$
2. foreach $v \in V$ do
3. \hspace{1em} $v.visited \leftarrow False$
4. for $i \leftarrow 1$ to $|O|$ do
5. \hspace{2em} if $v$ has edge with bootstrapped vertices $O$ then
6. \hspace{3em} $v.d[i] \leftarrow 1$
7. \hspace{2em} else
8. \hspace{3em} $v.d[i] \leftarrow \infty$
9. for $i \leftarrow 1$ to $|O|$ do
10. \hspace{1em} visits $\leftarrow \lceil \frac{|V|}{|O|} \rceil$
11. if $O[i].visited = False$ then
12. \hspace{1em} Append $O[i]$ to $L$
13. \hspace{1em} $O[i].visited \leftarrow True$
14. \hspace{1em} visits $\leftarrow visits - 1$
15. while visits > 0 and $L$ is not full do
16. \hspace{1em} Find $u \in V$ with minimum $u.d[i]$ and $u.visited = False$
17. \hspace{2em} Append $u$ to $L$
18. \hspace{2em} $u.visited \leftarrow True$
19. \hspace{2em} visits $\leftarrow visits - 1$
20. foreach $w \in$ neighbors of $u$ do
21. \hspace{2em} if $w.visited = False$ and $u.d[i] + 1 < w.d[i]$ then
22. \hspace{3em} $w.d[i] \leftarrow u.d[i] + 1$
```

C TWO-PHASE OFFLINE TRAINING ILLUSTRATION

We use Figure 20 to illustrate why the two-phase training can effectively accelerate the training. Here we only consider the two-dimensional preference space with two performance metrics, throughput and latency, for visual simplicity. Each point in this figure shows a certain objective (a combination of throughput and latency requirements) and the distance to the origin point shows the effectiveness (i.e., how optimally the model can act) of the model.

The dash curve is convex converge set (CCS), which represents the optimal solution of the task. The solid curve represents the effectiveness of our model. The goal of training is to make the effectiveness (solid line) of our model approach the optimality (dash line).

After the bootstrapping phase, we have a set of solutions for certain set of objectives, shown as pivot points in the figure. These points are: 1) uniformly distributed, and 2) very close to optimality. The training is also fast because the set
is small. Then, in the fast traversing phase, we will determine the rest of the points. Because we already have those pivot points, we can have a very good starting point during training and the effectiveness will not be far away from optimality. Meanwhile, the training can be effectively accelerated by using the information provided by pivot points.
