Abstract—In this paper, diagnosability is characterized for a labeled max-plus automaton $\mathcal{A}^D$ over a dioid $D$ as a real-time system. In order to represent time elapsing, a special class of dioids called progressive are considered, in which there is a total canonical order, there is at least one element greater than 1, the product of sufficiently many elements greater than 1 is arbitrarily large, and the cancellative law is satisfied. Then a notion of diagnosability is formulated for $\mathcal{A}^D$ over a progressive dioid $D$. By developing a notion of concurrent composition, a sufficient and necessary condition is given for diagnosability of automaton $\mathcal{A}^D$. It is also proven that the problem of verifying diagnosability of $\mathcal{A}^D$ is coNP-hard even holds for deterministic, deadlock-free, and divergence-free $\mathcal{A}^D$, where $\mathbb{Q}$ and $\mathbb{N}_0$ are the max-plus dioids having elements in $\mathbb{Q} \cup \{-\infty\}$ and $\mathbb{N}_0 \cup \{-\infty\}$, respectively.

I. INTRODUCTION

A. Background

The study of diagnosability of discrete-event systems (DESs) modeled by finite-state machines originates from [1], [2], where in the former state-based diagnosis was studied, and in the latter event-based diagnosis was studied and a formal definition of diagnosability was given. A DES usually consists of discrete states and transitions between states caused by spontaneous occurrences of partially-observed (labeled) events. Intuitively, a DES is called diagnosable if the occurrence of a faulty event can be determined after a finite number of subsequent events occur by observing the generated output sequence. Widely studied DES models have finitely many events, but may have infinitely many states, e.g., Petri nets, timed automata, max-plus systems, etc. The event-based notion of diagnosability can be naturally extended to these models, although the characterization of diagnosability is much more difficult than in finite-state machines.

B. Literature review

In the following, we briefly review diagnosability results in different models.

Finite-state automata. In finite-state automata (FSAs), a notion of diagnosability was formulated in [2], and a diagnoser method was proposed to verify diagnosability. The diagnoser of an FSA records state estimates along observed output sequences and also records fault propagation along transitions of states of the FSA. The diagnoser has exponential complexity, and diagnosability is verifiable by a relatively simple cycle condition on the diagnoser. Hence diagnosability can be verified in EXPTIME. Later, a twin-plant structure with polynomial complexity was proposed in [3], [4] so that a polynomial-time algorithm for verifying diagnosability was given. The verification algorithms in the above three papers all depend on two fundamental assumptions of deadlock-freeness (an FSA will always run) and divergence-freeness (the running of an FSA will always be eventually observed, more precisely, for every infinitely long transition sequence, its output sequence is also of infinite length). Later on, in many papers, verification of all kinds of variants of diagnosability depends on the two assumptions. The two assumptions were removed in [5] by using a generalized version of the twin-plant structure to verify negation of diagnosability, in polynomial time. Results on diagnosability of probabilistic FSAs can be found in [6], [7], [8], etc. Results on decentralized settings of diagnosability can be found in [9], [10], [11], etc.

Labeled Petri nets. For results on diagnosability of labeled Petri nets, we refer the reader to [12], [13], [14], etc. In [12], a new technique called verifier (which can be regarded as the twin-plant structure extended to labeled Petri nets) was developed to verify diagnosability, and two notions of diagnosability were verified by using the technique under several assumptions. It was also pointed out that the two notions are equivalent in FSAs but not in labeled Petri nets. In [14], the weaker notion of diagnosability studied in [12] was proven to be decidable with an EXPSPACE lower bound under the first of the two previously mentioned assumptions, by using the verifier and Yen’s path formulae [15], [16]; in [13], an even weaker notion of diagnosability called trace diagnosability was proven to be decidable in EXPSPACE with an EXPSPACE lower bound without any assumption, by using the verifier and linear temporal logic. Results on diagnosability in special classes (e.g., bounded, unobservable-event-induced-subnets being acyclic) of labeled Petri nets can be found in [17], [18], [19], etc.

Labeled timed automata. Diagnosability was firstly defined for (labeled) timed automata in [20], and its decision problem was proven to be PSPACE-complete, where PSPACE-membership was proved by computing a parallel composition (which falls back on the generalized twin-plant structure of FSAs used in [5]) in time polynomial in the size of the timed automaton and finding Zeno runs of the parallel composition in PSPACE in the size of the parallel composition. The diagnoser of a timed automaton was defined (which may be a Turing machine) and fault diagnosis was done in 2-EXPTIME in the size of the timed automaton and in the size of the observation. In [21], it was studied whether a timed automaton has a diagnoser that can be realized by a deterministic timed automaton (or particularly an event recording automaton as a subclass of the former). The former was proven to be 2-EXPTIME-complete.
and the latter PSPACE-complete, provided that a bound on the resources available to the diagnoser is given.

Labeled max-plus automata. In [22], a notion of diagnoser was defined for a (labeled) max-plus automaton over the max-plus dioid \( \mathbb{R} = (\mathbb{R} \cup \{-\infty\}, \max, +, -\infty, 0) \), where \( \mathbb{R} \) denotes the set of real numbers, and computed under the second of the previously mentioned two assumptions and an additional strong assumption that for every two different states \( p, q \), there is at most one unobservable transition from \( p \) to \( q \). In the paper, a max-plus automaton was not treated as a real-time system as above but a max-plus system, because the diagnoser does not record state estimates along observed timed output sequences. Given a timed output sequence \( \gamma = (\sigma_1, t_1) \ldots (\sigma_n, t_n) \), when the diagnoser receives \( \gamma \), it does not necessarily return the ending states of the runs that produce output \( \sigma_i \) at time \( t_i \), where \( 1 \leq i \leq n \), but returns the ending states of the runs who produce output sequence \( \sigma_1 \ldots \sigma_n \) and have the maximal time consumption equal to \( t_i \) for generating \( \sigma_1 \ldots \sigma_i \). In addition, it was not pointed out that generally for the above max-plus dioid \( \mathbb{R} \), a diagnoser is usually uncomputable. Finally, a notion of diagnosability was not formulated.

C. Contribution of the paper

In this paper, we regard a labeled max-plus automaton \( \mathcal{A}^D \) over a dioid \( D \) as a real-time system and characterize a notion of diagnosability.

1) In order to represent time elapsing, we consider a special class of dioids which we call progressive. Intuitively in this class, there is a total canonical order, there is at least one element greater than 1, the product of sufficiently many elements greater than 1 is arbitrarily large, and the cancellative law is satisfied. The classical max-plus dioids such as the tropical semiring \( \mathbb{R}^\infty_{+, \max, +, -\infty, 0} \), and \( \mathbb{N}_0 = (\mathbb{N}_0 \cup \{-\infty\}, \max, +, +, -\infty, 0) \) are all progressive.

2) For a labeled max-plus automaton \( \mathcal{A}^D \) over a progressive dioid \( D \), we give a formal definition of diagnosability (Definition 3.1). In order to conveniently represent the definition, we choose runs but not traces (i.e., generated event sequences) as in almost all results in the literature (see Section I-B).

3) By developing a new notion of concurrent composition (Definition 3.5) for automaton \( \mathcal{A}^D \), we give a sufficient and necessary condition for negation of diagnosability of \( \mathcal{A}^D \) (Theorem 3.12).

4) Particularly, we prove that the problem of verifying diagnosability of automaton \( \mathcal{A}^D \) over dioid \( D \) is coNP-complete (Theorem 3.15), where coNP-hardness even holds for deterministic, deadlock-free, and divergence-free automaton \( \mathcal{A}^D \). coNP-membership is obtained by proving that a concurrent composition can be computed in NP in the size of \( \mathcal{A}^D \) by connecting \( \mathcal{A}^D \) and the NP-complete exact path length problem [23], and negation of diagnosability can be verified in time polynomial in the size of the concurrent composition. coNP-hardness is obtained by constructing a polynomial-time reduction from the NP-complete subset sum problem [24] to negation of diagnosability.

Compared with the results given in [22], the results in our paper have several advantages: (1) We formulate a notion of diagnosability, (2) We regard a max-plus automaton as a real-time system, so that the occurrence of any faulty event will be diagnosed if an automaton is diagnosable. (3) The results in our paper do not depend any of the two fundamental assumptions as mentioned before, but the results in [22] depend on the second of the two assumptions and an additional strong assumption.

The remainder of the paper is structured as follows. In Section II, we introduce notation, basic facts, the exact path length problem, the subset sum problem, and labeled max-plus automata over dioids. We also propose a notion of progressive dioid and prove several useful properties in such dioids. In Section III, we show the main results of the paper. Section IV ends the paper with a short conclusion.

II. PRELIMINARIES

A. Notation

Symbols \( \mathbb{N}_0, \mathbb{Z}, \mathbb{Z}_+, \mathbb{Q}, \) and \( \mathbb{Q}_+ \) denote the sets of non-negative integers (natural numbers), integers, positive integers, rational numbers, and positive rational numbers, respectively. For a finite alphabet \( \Sigma, \Sigma^* \) denotes the set of words (i.e., finite sequences) over \( \Sigma \) including the empty word \( \epsilon \). Elements of \( \Sigma \) are called letters. For \( s \in \Sigma^* \) and \( \sigma \in \Sigma \), we write \( \sigma \in s \) if \( \sigma \) appears in \( s \); \( \Sigma^+ := \Sigma^* \setminus \{\epsilon\} \). For a word \( s \in \Sigma^* \), \( |s| \) stands for its length. For \( s \in \Sigma^+ \) and natural number \( k \), \( \text{last}(s) \) denotes its last letter, \( s^k \) denotes the concatenation of \( k \) copies of \( s \). For a word \( s \in \Sigma^* \), a word \( s' \in \Sigma^* \) is called a prefix of \( s \), denoted as \( s' \preceq s \), if there exists another word \( s'' \in \Sigma^* \) such that \( s = s's'' \). For \( s \in \Sigma^+ \) and \( s' \in \Sigma^* \), we use \( s \nsubsetneq s' \) to denote \( s \preceq s' \) and \( s \neq s' \). For a word \( s \in \Sigma^* \), a word \( s' \in \Sigma^* \) is called a suffix of \( s \) if \( s''s' = s \) for some \( s'' \in \Sigma^* \). For two real numbers \( a, b \in [a, b] \) denotes the closed interval with lower and upper endpoints being \( a \) and \( b \), respectively; for two integers \( i \leq j \), \( [i, j] \) denotes the set of all integers no less than \( i \) and no greater than \( j \); and for a set \( S \), \( |S| \) denotes its cardinality and \( 2^S \) its power set. \( \subset \) and \( \varsubsetneq \) denote the subset and strict subset relations.

We will use the NP-complete exact path length (EPL) problem and subset sum (SS) problem in the literature to prove the main results.

B. The exact path length problem

Consider a \( k \)-dimensional weighted directed graph \( G = (Q^k, V, A) \), where \( k \in \mathbb{Z}_+ \); \( Q^k = Q \times \cdots \times Q \), \( V \) is a finite set of vertices, \( A \subset V \times Q^k \times V \) a finite set of weighted edges with weights in \( Q^k \). For a path \( v_1 \xrightarrow{z_1} v_2 \xrightarrow{z_2} \cdots \xrightarrow{z_{n-1}} v_n \), its weight is defined by \( \sum_{i=1}^{n-1} z_i \). The EPL problem [23] is stated as follows.

Problem 1 (EPL): Given a positive integer \( k \), a \( k \)-dimensional weighted directed graph \( G = (Q^k, V, A) \), two vertices \( v_1, v_2 \in V \), and a vertex \( z \in Q^k \) determine whether there is a path from \( v_1 \) to \( v_2 \) with weight \( z \).
We set that for a positive integer $n$, the size $\text{size}(n)$ of $n$ to be the length of its binary representation, $\text{size}(0) = 1$; for a negative integer $-n$, $\text{size}(-n) = \text{size}(n) + 1$ (here 1 is used to denote the size of “-”); for a rational number $m/n$, where $m, n$ are relatively prime integers, $\text{size}(m/n) = \text{size}(m) + \text{size}(n)$; then for a vector $z \in \mathbb{Q}^k$, its size is the sum of the sizes of its components. The size of an instance $(k, G, v_1, v_2, z)$ of the EPL problem is defined by $\text{size}(k) + \text{size}(G) + 2 + \text{size}(z)$, where $\text{size}(G) = |V| + \text{size}(A)$, $\text{size}(A) = \sum_{(v_1, v_2) \in A} (2 + \text{size}(z'))$.

Lemma 2.1 ([23]): The EPL problem belongs to $\mathcal{NP}$. The EPL problem is $\mathcal{NP}$-hard already for graph $(\mathbb{Z}, V, A)$. Note that EPL problem studied in [23] is on graph $(\mathbb{Z}^2, V, A)$. However, the proof in [23] also applies to the more general case for graph $(\mathbb{Q}^k, V, A)$, resulting in Lemma 2.1.

C. The subset sum problem

The SS problem [24] is as follows.

Problem 2 (SS): Given positive integers $n_1, \ldots, n_m$, and $N$, determine whether $N = \sum_{i \in I} n_i$ for some $I \subset [1, m]$.

Lemma 2.2 ([24]): The SS problem is $\mathcal{NP}$-complete.

D. Dioids

Definition 2.3: An idempotent semiring (or dioid) is a set $T$ with two binary operations $\oplus$ and $\otimes$, called addition and multiplication, such that $(T, \oplus)$ is an idempotent commutative monoid with identity element $0 \in T$ (also called zero), $(T, \otimes)$ is a monoid with identity element $1 \in T$ (also called one), $0$ is absorbing, and $\otimes$ distributes over $\oplus$ on both sides. A dioid is denoted by $D = (T, \oplus, \otimes, 0, 1)$.

For $a \in D$ (i.e., $a \in T$), we write $a^n = a \otimes \cdots \otimes a$ for all $n \in \mathbb{N}_0$, and denote $a^0 = 1$.

An order over a set $T$ is a relation $\leq$ on $T \times T$ that is reflexive, anti-symmetric, and transitive.

For all $a, b \in T$ such that $a \leq b$, we also write $b \geq a$. If additionally $a \neq b$, then we write $a < b$ or $b > a$.

In dioid $D$, the relation $\leq$ on $T \times T$ such that $a \leq b$ if and only if $a \otimes b = b$ for all $b \in T$ is an order (called the canonical order). In the sequel, $\leq$ always means the canonical order. Order $\leq$ is total if for all $a, b \in D$, either $a \leq b$ or $b \leq a$.

We have some direct properties as follows.

Lemma 2.4:

1. Let $a, b \in D$ be such that $1 \leq b$. Then for all $a \in D$, $a \leq a \otimes b$.
2. Let $a, b \in D$ be such that $1 < a$ and $1 \leq b$. Then $1 < a \otimes b$.
3. Let $a, b, c, d \in D$ be such that $a \leq b$ and $c \leq d$. Then $a \otimes c \leq b \otimes d$.
4. Let $a, b \in D$ be such that $1 < a < b$. Then $a < a \otimes b$.
5. Let $a, b \in D$ be such that $1 > a > b$. Then $a > a \otimes b$.

The results in Lemma 2.4 show that a dioid has some features of time elapsing, if we consider an element greater than 1 as a positive time elapsing (1 means no time elapses), and also consider the product of two elements greater than 1 as the total time elapsing (see (4)). In order to see whether a dioid has more features of time elapsing, one may ask given $a, b \in D$ such that $1 < a < b$, is it true that $(a) b < b \otimes a$ and $(b) a < a^2$? Generally not. Consider dioid

$$\left(\mathbb{Z} \cup \{-\infty, +\infty\}, \max, +, -\infty, 0\right),$$

where $+\infty$ is the maximal element. For $0 < 1 < +\infty$, one does not have $(+\infty) < (+\infty) + 1$ or $+\infty < (+\infty) + (+\infty)$, but one has $1 < 1 + 1$.

In this paper, we consider dioids that have more features of time elapsing as possible, because we want to use a dioid to describe the time in a max-plus automaton as a real-time system. To this end, we consider dioids with the above properties (a) and (b) and additionally with the cancellative law: for all $a, b, c \in T$ with $a \neq 0$, $a \otimes b = a \otimes c \implies b = c$ and $b \otimes a = c \otimes a \implies b = c$. A dioid with the cancellative law is called cancellative.

Lemma 2.5: Consider a cancellative dioid $D$. For all $a, b, c, d \in D$, the following hold.

1. If $a \otimes b \geq a \otimes c$ and $a \neq 0$, then $b \geq c$.
2. If $c \otimes d \geq a \otimes b$, $c \leq a$, and $a \neq 0$, then $d \geq b$.
3. If $a \neq 0$ and $b > c$ then $a \otimes b > a \otimes c$ and $b \otimes a > c \otimes a$.

Proof: We only prove (2). By $c \leq a$ we have $c \oplus a = a$. Then $a \otimes d = (c \oplus a) \otimes d = c \otimes d \oplus a \otimes d \geq a \otimes b = a \otimes (b \otimes d)$. By the cancellative law, $d \geq b \otimes d$. Furthermore, we have $d = b \otimes d$. idempotence. Hence $d \geq b$.

Now we give the notion of progressive dioid.

Definition 2.6: A dioid $D = (T, \oplus, \otimes, 0, 1)$ is called progressive if (1) $D$ has a total canonical order, (2) $D$ has at least one element greater than 1, (3) for all $a, b \in D$ with $a > 1$ and $b > 1$, there exists $n \in \mathbb{Z}_+$ such that $a^n > b$, (4) for all $a, b \in D$ with $a < 1$ and $b < 1$, there exists $n \in \mathbb{Z}_+$ such that $a^n < b$, (5) $D$ is cancellative, (6) for all $a, b \in D$ with $a < 1 < b$, there exists $n, m \in \mathbb{Z}_+$ such that $a \otimes b^n > b$ and $b \otimes a^m > a$, (7) for all $a, b \in D$ with $a < 1 < b$, there exists $n, m \in \mathbb{Z}_+$ such that $a^n \otimes b < 1$, $b \otimes a^m < 1$, and (8) $D$ has no zero divisor (i.e., for all nonzero $a, b \in D$, $a \otimes b \neq 0$).

Remark 1: If in $D$, every nonzero element $a$ has a (unique) multiplicative inverse $a^{-1}$, then (3) (resp., (6)) is equivalent to (4) (resp., (7)), because in this case if $a \otimes b = 1$, then $a > 1 \iff b < 1 \iff a^{-1} < b^{-1}$.

Lemma 2.7: Let $D$ be a progressive dioid.

1. Let $a, b \in D$ be such that $1 < a$ and $1 < b$. Then $a < a \otimes b$ and $a < b \otimes a$.
2. Let $a, b \in D$ be such that $1 > a$ and $1 > b$. Then $a > a \otimes b$ and $a > b \otimes a$.

Proof: We only need to prove (1). (2) is a symmetric form of (1). By (1) of Lemma 2.4, we have $a \leq a \otimes b$ and $a \leq b \otimes a$.

Suppose $a = a \otimes b$. Then we have $a \otimes b = a \otimes b^2 = a$. Analogously we have $a \otimes b^n = a$ for all $n \in \mathbb{Z}_+$. Because $D$ is progressive, we have $b^m > a$ for some $m \in \mathbb{Z}_+$. By (4) of Lemma 2.4, we have $a < a \otimes b^m$, which is a contradiction. Hence $a < a \otimes b$. Similarly $a < a \otimes a$. \qed

Corollary 2.8: Let $D$ be a progressive dioid. Let $a, b \in D$ be such that $b < 1 < a$. Then

$$a < a^2 < a^3 < \cdots,$$
Remark 2: By Corollary 2.8, one sees in a progressivity dioid \( D \), the maximal element must not exists, that is, \( \ominus_{\text{te}T} \neq T \). For example, dioid (1) is not progressive.

One sees that the dioids

\[
\begin{align*}
P_\ominus &:= (\{0\} \cup \{q\}, \max, +, -\infty, 0), \\
Q_{\ominus} &:= (\{0\} \cup \{\ominus\}, \max, +, -\infty, 0), \\
\bar{Q}_\ominus &:= (\{0\} \cup \{\ominus\}, \max, +, -\infty, 0)
\end{align*}
\]

are progressive and have a total canonical order \( \leq \).

E. Labeled max-plus automata over \( D \)

A max-plus automaton is a tuple \( \mathcal{A} = (Q, E, \Delta, Q_0, \alpha, \mu) \) over dioid \( D = (T, \oplus, 0, 1) \), denoted by \( (D, \mathcal{A}) \) for short, where \( Q \) is a nonempty finite set of states, \( E \) a nonempty finite alphabet (elements of \( E \) are called events), \( \Delta \in Q \times E \times Q \) a transition relation (elements of \( \Delta \) are called transitions), \( Q_0 \subseteq Q \) is a nonempty set of initial states, \( \alpha \) is a map \( q \mapsto \alpha(q) \). We call an automaton deterministic if \( |Q_0| = 1 \) and for all \( q, q' \in Q \) and \( e \in E \), \( (q, e, q') \in \Delta \) if and only if \( (q, e, q'') \in \Delta \), \( q' = q'' \). For all \( q \in Q \), we also regard \( q \mapsto \delta(1) q \) as a transition (which is called an \( \epsilon \)-transition). A transition \( q \mapsto \delta(q) q' \) is called instantaneous if \( \delta(q) = 1 \), and called noninstantaneous if \( \delta(q) \neq 1 \). We call a state \( q \in Q \) dead state if for all \( q' \in Q \) and \( e \in E \), \( (q, e, q') \in \Delta \), i.e., there exists no transition starting at \( q \) (apart from the \( \epsilon \)-transition). Call an automaton \( (D, \mathcal{A}) \) deadlock-free if it has no reachable dead state.

For \( q_0, q_1, \ldots, q_n \in Q \), \( q_0 \) denotes its initial time delay, and in a transition \( q \mapsto \delta(q) q' \), \( \delta(q) \) denotes its time delay, i.e., the time consumption of the execution of the transition. Hence the execution of an instantaneous transition requires zero time, while the execution of a noninstantaneous transition requires a positive rational number \( \mu(q)q' \) as time.

For \( q_0, q_1, \ldots, q_n \in Q \) (where \( q_0 \) is not necessarily initial), and \( e_1, \ldots, e_n \in E \), where \( n \in N_0 \), we call

\[
\pi := q_0 \overset{e_1}{\rightarrow} q_1 \overset{e_2}{\rightarrow} \cdots \overset{e_{n-1}}{\rightarrow} q_n
\]

a path if for all \( i \in [0, n - 1] \), \( (q_i, e_{i+1}, q_{i+1}) \in \Delta \). We write \( \pi(\pi) = q_0 \), last(\( \pi) = q_n \). A path \( \pi \) is called a cycle if \( q_0 = q_n \). A cycle \( \pi \) is called simple if it has no repetitive states except for \( q_0 \) and \( q_n \). For paths \( \pi_1 \) and \( \pi_2 \), with last(\( \pi_1) = \text{init}(\pi_2) \), we use \( \pi_1 \pi_2 \) to denote the concatenation of \( \pi_1 \) and \( \pi_2 \) after removing one of last(\( \pi_1) \) or init(\( \pi_2) \), and write (\( \pi_1 \pi_2) \pi_1 \). The set of paths starting at \( q_0 \) in \( Q \) ending at \( q \in Q \) (under event sequence \( s := e_1 \cdots e_n \in E^+ \)) is denoted by \( q_0 \leadsto q \) \( q_0 \leadsto q \) \( q_0 \leadsto q \) \( q_0 \leadsto q \). Then for \( q \in Q \) and \( s \in E^*, \) we denote \( Q_0 \leadsto q := \bigcup_{q_0 \in Q_0} q_0 \leadsto q \) and \( Q_0 \leadsto q := \bigcup_{q_0 \in Q_0} q_0 \leadsto q \).

The timed word of path \( \pi \) is defined by

\[
(\pi(t)) := (e_1(t), e_2(t), \ldots, e_n(t)),
\]

where for all \( i \in [1, n] \), \( t_i = \otimes_{j=1}^i \mu(e_j)q_{j-1}q_j \). The weight WT\( (\pi) \) (also denoted by WT\( (\pi) \)) of path \( \pi \) and the weight WT\( (\pi(t)) \) (also denoted by WT\( (\pi(t)) \)) of timed word \( \pi(t) \) are both defined by \( t_0 \). Particularly, we set WT\( (\pi) = 1 \) for the empty path \( \epsilon \). A path always has nonzero weight if \( D \) has no zero divisor. A path \( \pi \) is called instantaneous if \( t_1 = \cdots = t_n = 1 \), and called noninstantaneous otherwise. Call a state \( q \in Q \) stuck if either \( q \) is dead or starting at \( q \) there exist only instantaneous paths. Automaton \( (D, \mathcal{A}) \) is called stuck-free if it has no reachable stuck state.

Particularly for \( \otimes_{\geq 0}, \), one has \( t_i = \sum_{j=1}^i \mu(e_j)q_{j-1}q_j \), hence \( t_i \) denotes the time needed for the first \( i \) transitions in path \( \pi(t) \).

We define a labeling function \( \ell : E \to \mathbb{S} \cup \{\epsilon\} \), where \( \mathbb{S} \) is a finite alphabet, to distinguish observable and unobservable events. The set of observable events and the set of unobservable events are denoted by \( E_o = \{e \in E | \ell(e) \in \mathbb{S} \} \) and \( E_uo = \{e \in E | \ell(e) = \epsilon \} \). When an observable event \( e \) occurs, one observes \( \ell(e) \); while an unobservable event occurs, one observes nothing. A transition \( q \mapsto \delta(q)e \) is called observable (resp., unobservable) if \( e \) is observable (resp., unobservable). Labeling function \( \ell \) is recursively extended to \( E^* \to \mathbb{S}^* \) as \( \ell(e_1 \cdots e_n) = \ell(e_1)\ell(e_2) \cdots \ell(e_n) \). A path \( \pi(t) \) is called unobservable if \( \ell(e_1 \cdots e_n) = \epsilon \), and called observable otherwise.

A labeled max-plus automaton is formulated as

\[
A^D := (D, \mathcal{A})
\]

Labeling function \( \ell \) is extended as follows: for all \( (e, t) \in \mathbb{S} \times T \), \( \ell((e, t)) = \ell(e) \) if \( \ell(e) \neq \epsilon \), and \( \ell((e, t)) = \epsilon \) otherwise. Hence \( \ell \) is also recursively extended to \( (\mathbb{S} \times T)^* \to (\mathbb{S} \times T)^* \). For a path \( \pi \), \( \ell(\pi(t)) \) is called a timed labeled output sequence. We also extend the previously defined function \( \tau \) as follows:

\[
\tau(\gamma) = (\pi_1(t_1), \ldots, \pi_n(t_n)),
\]

where \( t_j = \otimes_{i=1}^j t_i \) for all \( j \in [1, n] \). Particularly, \( \tau(\epsilon) = \epsilon \).

Remark 3: A finite-state automaton (studied in \([25, 26, 27, 28, \text{etc.})\] can be regarded as a labeled max-plus automaton \( \mathcal{A}^D \) such that all unobservable transitions have weight 0 and every two observable transitions with the same label have the same positive weight.

The size of a given automaton \( \mathcal{A}^D \) is defined by \( |Q| + |E| \times |Q_0| + \text{size}(\alpha) + \text{size}(\mu) + \text{size}(\ell) \), where the size of a rational number has already been defined before, \( \text{size}(\alpha) = \sum_{q_0 \in Q_0} \text{size}(\alpha(q_0)) \), \( \text{size}(\mu) = \sum_{(q, e, q') \in \Delta} \text{size}(\mu(q)q') \), \( \text{size}(\ell) = \{|(e, \ell(e))| e \in E \} \).

From now on, without loss of generality, we assume for each initial state \( q_0 \in Q_0 \), \( \alpha(q_0) = 1 \), because otherwise we can add a new initial state \( q_0' \) not in \( Q_0 \) and set \( \alpha(q_0') = 1 \), and for each initial state \( q_0 \in Q_0 \) such that \( \alpha(q_0) \neq 1 \) we add a new transition \( q_0' \mapsto \delta(q_0)q_0 \), and set \( q_0 \) to be not initial any more, where \( \delta \) is a new event not in \( E \). For consistency we also assume that \( \ell(\epsilon) = \epsilon \).
Particularly for $A^{2}_{\text{max}}$, if it generates a path $\pi$ as in (5) such that $q_0 \in Q_0$, consider its timed word $\tau(\pi)$ as in (6), then at time $t_\pi$, one will observe $\ell(e_i)$ if $\ell(e_i) \neq \epsilon$; and observe nothing otherwise, where $i \in [1, n]$.

**Example 1:** A stuck-free labeled max-plus automaton $A^{0}_{\text{max}}$ is shown in Fig. 1.

![Fig. 1. A labeled max-plus automaton $A^{0}_{\text{max}}$ over dioid $\mathbb{N}_0$, where $q_0$ is the unique initial state, $a$ is the observable event, $u$, $f$ are unobservable events, and $q$ is the unique faulty event](image)

**III. MAIN RESULTS**

**A. The definition of diagnosability**

In this subsection, we formulate the definition of diagnosability for labeled max-plus automaton $A^D$ (7). The set of faulty events is denoted by a subset $E_f$ of $E$. Usually, one assumes that $E_f \subset E_{\text{wo}}$ [2], [20], [3], because the occurrence of observable events can be directly seen. However, technically, this assumption is usually not needed. We do not make this assumption in this paper, because different observable events may have the same label (i.e., labeling function $\ell$ is not necessarily injective on $E_{\text{wo}}$), so the occurrences of observable faulty events may also need to be distinguished. As usual, with slight abuse of notion, for $s \in E^*$, we use $E_f \subset s$ to denote that some faulty event $e_f \in E_f$ appears in $s$. Similarly for $w \in (E \times T)^*$, we use $E_f \subset w$ to denote that some $(e_f, t)$ appears in $w$, where $e_f \in E_f$, $t \in T$. In $A^D$, all transitions of the form $q_1 \xrightarrow{e_f, \mu(e_f)} q_2$ for some $e_f \in E_f$ are called faulty transitions, the other transitions are called normal transitions. We denote by $A^D_n$ the normal subautomaton of $A^D$ obtained by removing all faulty transitions of $A^D$. We also denote by $A^D_p$ the faulty subautomaton of $A^D$ by only keeping all faulty transitions and their predecessors and successors, where predecessors mean the transitions from which some faulty transition is reachable, and successors mean the transitions that are reachable from some faulty transition.

**Definition 3.1:** Let $D$ be a progressive dioid, $A^D$ a labeled max-plus automaton as in (7) and $E_f \subset E$ a set of faulty events. $A^D$ is called $E_f$-diagnosable (see Fig. 2 for illustration) if

\[
\begin{align*}
(\exists t \in D : t > 1)(\forall \pi \in Q_0 \xrightarrow{\text{se}} q \text{ with } e_f \in E_f) \\
(\forall \pi' \in q \xrightarrow{q'} q_0)[[(\text{WT}_{\pi'} > t) \lor (q' \text{ is stuck})] \implies D],
\end{align*}
\]

where $D = \{(\forall \pi'' \in Q_0 \xrightarrow{q''} q'' \text{ with } \ell(\pi''') = \ell(\pi(\pi'')) \lor (q'' \text{ is stuck})) \implies (E_f \in s''')\}$.

**Definition 3.1** can be interpreted as follows. For a progressive dioid $D$, automaton $A^D$ is $E_f$-diagnosable if and only if there exists an element $t > 1$ in $D$, for every path $\pi$ whose last event is faulty, for every path $\pi'$ as a continuation of $\pi$, if either $\text{WT}_{\pi'} > t$ or $\pi'$ ends at a stuck state, then one can make sure that a faulty event (although not necessarily $e_f$) must have occurred when the timed label sequence $\ell(\pi(\pi'))$ has been generated after at least time $t$ since $e_f$ occurs. Here we consider progressive dioids because in such dioids, for a path $\pi'$ as in (9), in a large extent we have $\text{WT}_{\pi'} > t$, i.e., automaton $A^D$ can run for a long time.

![Fig. 2. Illustration of diagnosability](image)

Particularly, the $E_f$-diagnosability of $A^{2\text{max}}$ has the following practical meaning: if $A^{2\text{max}}$ is $E_f$-diagnosable, then once a faulty event (e.g., $e_f$) occurs at some instant (e.g., $\text{WT}_\pi$), then after a sufficiently long time (e.g., $t \in Q_+$) that only depends on $A^{2\text{max}}$, one can make sure that some faulty event must have occurred on observing the generated timed label sequence (e.g., $\ell(\pi(\pi'))$) at every instant $\geq t$ since $e_f$ occurs, no matter whether $q'$ is a stuck state.

In order to reduce complicated discussions when characterizing $E_f$-diagnosability of automaton $A^D$, we can equivalently simplify its definition shown in (9) by adding at each stuck state a normal, noninstantaneous, and unobservable transition to a sink state on which there is also a normal, noninstantaneous, and unobservable self-loop. Let the labeled stuck-free max-plus automaton $A^D_{\text{sf}}$ (10) be obtained from $A^D$ by doing the following modifications on $A^D$: at each stuck state $q \in Q$, add a $u_q$-transition $q \xrightarrow{u_q/t} q$, where $u_q$ is a normal, unobservable event not in $E$, $q$ is a fresh state not in $Q$, $1 > t \in D$, and add a self-loop $q \xrightarrow{u_q/t} q$.

**Lemma 3.2:** Let $D$ be a progressive dioid. Let $A^D$ be a labeled max-plus automaton as in (7) and $E_f \subset E$ a set of faulty events. Let $A^D_{\text{sf}}$ be its stuck-free automaton as in (10). Then $A^D_{\text{sf}}$ is $E_f$-diagnosable if and only if $A^D_{\text{sf}}$ satisfies

\[
\begin{align*}
(\exists t \in D : t > 1)(\forall \pi \in Q_0 \xrightarrow{\text{se}} q \text{ with } e_f \in E_f) \\
(\forall \pi' \in q \xrightarrow{q'} Q)[[(\text{WT}_{\pi'} > t) \implies D],
\end{align*}
\]

where $D = \{(\forall \pi'' \in Q_0 \xrightarrow{q''} q'' \text{ with } \ell(\pi''') = \ell(\pi(\pi'')) \lor (q'' \text{ is stuck})) \implies (E_f \in s''')\}$.

**Proof** Observe that in a path $\pi$ of $A^D_{\text{sf}}$, if $u_q$ appears, then after the $u_q$, only $q$ can be visited, hence all successors are $q \xrightarrow{u_q/t} q$. Without loss of generality, we assume that $A^D$
is not stuck-free, otherwise $A^T$ is the same as its stuck-free automaton $\bar{A}^T$.

“only if”:

Suppose that $A^T$ is $E_f$-diagnosable, i.e., (9) holds. Choose a $t > 1$ as in (9). In $\bar{A}^T$, arbitrarily choose paths $\pi \in Q \xrightarrow{\alpha} q, \pi' \in q \xrightarrow{\alpha'} q'$, and $\pi'' \in Q \xrightarrow{\alpha''} q''$ such that $e_f \in E_f, W T_{\pi'} > t, \ell(\tau(\pi'')) = \ell(\tau(\pi\pi'))$, and $WT_{\pi''} \geq WT_{\pi' \otimes \pi}$. Let $\bar{\pi}'' \in Q \xrightarrow{\alpha''} q''$ be the longest prefix of $\pi''$ that contains no $u_0$. Then $\pi''$ is a path of $A^T$ and $\ell(\tau(\bar{\pi}'')) = \ell(\tau(\pi\pi'))$. In addition, last($\bar{\pi}'')$ is a stuck state of $A^T$ if $\bar{\pi}''$ is not the same as $\pi''$.

(i) Assume $u_0 \notin \mathit{se}_f s'$. Then $\pi''$ is also a path of $A^T$, and hence $E_f \in s''$ by (9). It follows that $E_f \in s'$.

(ii) Assume $u_0 \notin \mathit{se}_f$ and $u_0 \in s'$. Then $\pi$ is also a path of $A^T$. Let $\bar{\pi}'$ be the longest prefix of $\pi$ that contains no $u_0$, then $\pi\pi'$ is a path of $A^T$, $\ell(\tau(\pi\pi')) = \ell(\tau(\pi\pi'))$, and last($\bar{\pi}'$) is a stuck state of $A^T$ if $\pi'$ is not the same as $\pi''$. We then have $\ell(\tau(\bar{\pi}')) = \ell(\tau(\pi\pi'))$. Then by (9), we have $E_f \in s''$. It also follows that $E_f \in s'$.

(iii) By definition of $A^T$, $u_0 \notin \mathit{se}_f s'$. Based on the above (i), (ii), and (iii), no matter whether $u_0 \in \mathit{se}_f s'$ or not, one has $E_f \in s''$, then (11) holds.

“if”:

Suppose $\bar{A}^T$ satisfies (11). Choose a $t > 1$ as in (11). In $A^T$, arbitrarily choose paths $\pi \in Q \xrightarrow{\alpha} q, \pi' \in q \xrightarrow{\alpha'} q'$, and $\pi'' \in Q \xrightarrow{\alpha''} q''$ such that $e_f \in E_f, WT_{\pi'} > t$ or $q'$ is stuck, $\ell(\tau(\pi'')) = \ell(\tau(\pi\pi'))$, and last($\bar{\pi}'$) is a stuck state of $A^T$ if $\pi'$ is not the same as $\pi''$. We directly see that $\pi''$ and $\pi''$ are paths of $A^T$. If $WT_{\pi'} > t$, then $q'$ is stuck, we denote $\bar{\pi}' := \pi' \left(\frac{u_0}{n} \frac{n}{2^m}\right)$, where $n \in \mathbb{Z}_+$ is such that $WT_{\pi'} \otimes n > 1$ and $n > t (n$ exists because $D$ is progressive), $t \mu (u_0)_{q} > 1$ (see (10)), then $WT_{\pi'} = WT_{\pi'} \otimes 2^m \geq t > t$ by Lemma 2.4. Similarly, if $WT_{\pi''} \geq WT_{\pi' \otimes \pi} \otimes n > t$ is stuck, we can add sufficiently many $u_0$-transitions after $q''$ so that the updated $\pi''$ satisfies $WT_{\pi''} \geq WT_{\pi' \otimes \pi}$. Then by (11), $e_f \in s''$.

By Lemma 3.2, in order to investigate whether a labeled max-plus automaton $A^T$ over a progressive dioid $D$ is $E_f$-diagnosable (Definition 3.1), we only need to investigate whether its stuck-free automaton $A^T$ satisfies the following Definition 3.3. In the sequel, $E_f$-diagnosability always means Definition 3.3. Apparently, Definition 3.3 is simpler than Definition 3.1.

**Definition 3.3:** Let $D$ be a progressive dioid, $A^T$ a labeled stuck-free max-plus automaton as in (7), and $E_f \subset D$ a set of faulty events. $A^T$ is called $E_f$-diagnosable if

\[(\exists t \in D : t > 1)(\forall \pi \in Q \xrightarrow{\alpha} q \text{ with } e_f \in E_f)(\forall \pi' \in q \xrightarrow{\alpha'} Q)[(WT_{\pi'} > t) \implies D],\]

where $D = (\forall \pi'' \in Q \xrightarrow{\alpha''} q'' \text{ with } \ell(\tau(\pi'')) = \ell(\tau(\pi\pi')))[(WT_{\pi''} \geq WT_{\pi' \otimes \pi}) \implies (E_f \in s'')]$.

By Definition 3.3, one directly has the following result.

**Proposition 3.4:** Let $D$ be a progressive dioid. A labeled max-plus automaton $A^T$ (7) is not $E_f$-diagnosable if and only if

\[(\forall t \in D : t > 1)(\exists \pi_t \in Q \xrightarrow{\alpha} q \text{ with } e_f \in E_f)(\exists \pi_t' \in q \xrightarrow{\alpha'} Q)(\exists \pi_t'' \in Q \xrightarrow{\alpha''} q'' \text{ such that } (WT_{\pi_t''} > t) \land (\ell(\tau(\pi_t'')) = \ell(\tau(\pi_t\pi_t')) \land (WT_{\pi_t''} \geq WT_{\pi_t' \otimes \pi} \otimes t) \land (E_f \notin s''))].\]

**Example 2:** Recall the automaton $\bar{A}^{N_0}$ in Example 1 (shown in Fig. 1). We choose paths

\[\pi_1 := q_0 \xrightarrow{a/3} q_1, \quad \pi'_1 := q_1 \xrightarrow{a/1} q_3 \xrightarrow{t} q_3,\]
\[\pi_2 := q_0 \xrightarrow{a/1} q_3 \xrightarrow{t+1} q_4,\]

where $t \in \mathbb{Z}_+$. It holds that

\[\ell(\tau(\pi_2'')) = \ell(\tau(\pi_1\pi_1')) = (a, 4)(a, 5) \ldots (a, t + 4).

Then $\bar{A}^{N_0}$ is not $\{f\}$-diagnosable by Proposition 3.4.

**B. The notion of concurrent composition**

In order to give a sufficient and necessary condition for $E_f$-diagnosability of a labeled (stuck-free) max-plus automaton $A^T$, we define a notion of concurrent composition (similar but technically different structures have been used to study diagnosability of finite-state automata [5] and timed automata [20]) of its faulty subautomaton $A^T$ and its normal subautomaton $A_n^T$. From now on, $A_n^T$ always means a stuck-free automaton.

**Definition 3.5:** Consider a labeled max-plus automaton $A^T$ (7) and a faulty event set $E_f \subset D$. We define the concurrent composition of $A^T$ and $A_n^T$ by a labeled finite-state automaton

\[CC_A(A^T, A_n^T) = (Q', E', \delta', Q_0', \Sigma', \ell'),\]

where $Q' = Q \times Q; E' = E_0' \cup E_0''$, where $E_0' = \{(\ell(e), e_2) \in E_0 \times (E_0 \times E_0'[\ell(e) = \ell(e_2)])\}; E_0'' = \{(\ell(e), \ell(e_2))|\ell(e) \in E_0'' \otimes E_0[\ell(e) = \ell(e_2)]\}; Q_0' = Q_0 \times \{q_{0'}\}; \delta' \subset Q' \times E' \times Q'$ is the transition relation, for all states $(q_1, q_2), (q_3, q_4) \in Q'$, events $(e_1, e_2) \in E_0', (e_1', e_2') \in E_0''$, and $\ell(e_1, e_2) = (e_1', e_2')$ in $E_0''$.

(1) (observable transition) $(\pi_1, q_2), (e_1, e_2)$ in $\ell'$ if and only if in $A^T$, there exist states $q_5, q_6 \in Q$, event sequences $s_1, s_2 \in (E_0')^*$, $s_2 \in (E_0'' \otimes E_0'[\ell(e) = \ell(e_2)])^*$, and paths

\[\pi_1 := q_1 \xrightarrow{s_1} q_5 \xrightarrow{e_1} q_3,\]
\[\pi_2 := q_2 \xrightarrow{s_2} q_6 \xrightarrow{e_2} q_4,\]

in $A^T$, $A_n^T$, respectively, such that $WT_{\pi_1} = WT_{\pi_2}$ (particularly when $D = \mathbb{Q}$, the weight of this transition is defined by 0 because $WT_{\pi_1} = WT_{\pi_2}$).

(2) (unobservable transition) $(\pi_1, q_2), (e_1', e_2')$ in $\ell'$ if and only if $(q_1, e_1', q_3) \in \Delta, q_2 = q_4$ (particularly when $D = \mathbb{Q}$, $\mu(e_1', e_2')$ is the weight of the transition).

(3) (unobservable transition) $(\pi_1, q_2), (e_1', e_2')$ in $\ell'$ if and only if $(q_1, e_1', q_3) \in \Delta, q_2 = q_4$ (particularly when $D = \mathbb{Q}$, $\mu(e_1', e_2')$ is the weight of the transition).
for all \((e_1, e_2) \in E'_o\), \(\ell'((e_1, e_2)) = \ell(e_1)\); for all \(e' \in E'_uo\), 
\(\ell'(e') = e\). \(\ell'\) is recursively extended to \((E')^* \to \Sigma^*\). For a state \(q'\) of \(CC_A(A_P^f, A_D^f)\), we write \(q' = (q'(L), q'(R))\).

One sees that in \(CC_A(A_P^f, A_D^f)\), an observable transition is obtained by merging two paths of \(A_D^f\), where the two paths contain exactly one observable event each, have the same weight and both end at the occurrences of the observable events; in addition, the second path contains only normal transitions. Hence the two paths are consistent with observations. Particularly for \(A^Q_{uo}\) in both paths, the observable events occur at the same instant of time if \(A^Q_{uo}\) starts at the starting states of the two paths at the same instant. However, an unobservable transition of \(CC_A(A_P^f, A_D^f)\) is obtained by merging an unobservable transition and an \(I\)-transition of \(A_D^f\). The two transitions are not necessarily consistent with observations, e.g., an unobservable transition may have weight \(\neq 1\), but an \(I\)-transition must have weight equal to 1. A sequence \(q_0 \xrightarrow{s_1} \cdots \xrightarrow{s_n} q_n\) of transitions of \(CC_A(A_P^f, A_D^f)\) \((n \in \mathbb{N}_0)\) is called a run. An unobservable run is a run consisting of unobservable transitions. In an unobservable run \(\pi\), its left component \(\pi'(L)\) is an unobservable path of \(A_D^f\), its right component \(\pi'(R)\) is an unobservable path of \(A_D^f\). We denote by \(CC_A(A_P^f, A_D^f)\) and \(CC_{uo}(A_P^f, A_D^f)\) the subautomata of \(CC_A(A_P^f, A_D^f)\) consisting of all observable transitions and all unobservable transitions, respectively.

Computing all unobservable transitions of \(CC_A(A_P^f, A_D^f)\) takes time polynomial in the size of \(A_D^f\). Now for states \((q_1, q_2), (q_3, q_4) \in Q'\) and observable event \((e_1, e_2) \in E'_o\), we check whether there exists an observable transition \(((q_1, q_2), (e_1, e_2), (q_3, q_4))\) in \(CC_A(A_P^f, A_D^f)\):

(i) Nondeterministically choose \(q_5, q_6 \in Q\) such that \(q_5 \xrightarrow{e_1} q_3\) and \(q_6 \xrightarrow{e_2} q_4\) are two observable transitions of \(A_P^f\) and \(A_D^f\), respectively.

(ii) Regard \(CC_{uo}(A_P^f, A_D^f)\) as a 1-dimensional weighted directed graph \((Q, V, A)\) as in Subsection II-B, where \(V = \{(p_1, p_2), \mu(e_{uo})_{p_1, p_3}, (p_3, p_2)\} \cup \{(p_1, p_2), -\mu(e_{uo})_{p_2, p_3}\} \cup \{(p_1, p_3), \mu(e_{uo})_{p_3, p_1}\}} \cup \{(p_2, p_3), -\mu(e_{uo})_{p_3, p_2}\} \in \Delta\}

(iii) If there exists a path from \((q_1, q_2)\) to \((q_3, q_6)\) with weight \(\mu(e_2)_{q_6, q_4} - \mu(e_1)_{q_3, q_5}\) in \(CC_{uo}(A_P^f, A_D^f)\), then \(((q_1, q_2), (e_1, e_2), (q_3, q_4))\) is an observable transition of \(CC_A(A_P^f, A_D^f)\).

By Lemma 2.1, the existence of such a path can be checked in NP. Hence the following result holds.

**Theorem 3.6:** Consider a labeled max-plus automaton \(A_D^f\), a faulty event set \(E_f \subseteq E\), and the corresponding faulty subautomaton \(A_P^f\) and normal subautomaton \(A_D^f\). The concurrent composition \(CC_A(A_D^f, A_D^f)\) can be computed in time nondeterministically polynomial in the size of \(A_D^f\).

In order to characterize \(E_f\)-distinguishability, we define several special kinds of transitions and runs in \(CC_A(A_P^f, A_D^f)\).

**Definition 3.7:** Consider an observable transition \((q_1, q_2) \xrightarrow{(e_1, e_2)} (q_3, q_4) =: \pi_{uo}\) of \(CC_A(A_P^f, A_D^f)\) as in Definition 3.5 (1), a path as \(\pi_1\) or \(\pi_2\) in (15) is called an admissible path of \(\pi_{uo}\). Transition \(\pi_{uo}\) is called faulty if it has an admissible path \(\pi_1\) containing a faulty event, called positive if it has an admissible path \(\pi_1\) such that \(WT_{\pi_1} > 1\). A run \(q'_0 \xrightarrow{e'_1} \cdots \xrightarrow{e'_n} q'_n\) of \(CC_A(A_P^f, A_D^f)\) is called positive if each transition \(q'_i \xrightarrow{e'_{i+1}} q'_{i+1}\) has an admissible path \(\pi_i\) such that \(\bigotimes_{i=0}^{n-1} WT_{\pi_i} > 1\). (Hence a positive observable transition is a positive run, a run consisting of positive observable transitions is a positive run by Lemma 2.4.) An unobservable transition of \(CC_A(A_P^f, A_D^f)\) is faulty if its event belongs to \(E_f \times \{\epsilon\}\).

In order to check in \(CC_A(A_D^f, A_D^f)\), whether an observable transition \(\pi_{uo}\) is faulty, we only need to add a condition \(E_f \times s_{1\epsilon_1}\) into (iii) so that we need to solve a subproblem of the EPF problem. Hence whether \(\pi_{uo}\) is faulty can be checked in NP in the size of \(A_D^f\). Similarly, whether \(\pi_{uo}\) is positive can also be checked in NP. Consider a simple cycle \(q'_0 \xrightarrow{e'_1} \cdots \xrightarrow{e'_n} q'_n\) of \(CC_A(A_D^f, A_D^f)\), where \(q'_0 = q'_n\). In order to check whether the cycle is positive, we can make \(n\) copies of \(CC_A(A_D^f, A_D^f)\), and use these copies and \(A_D^f\) to check for each \(i \in [0, n-1]\), whether \(q'_i \xrightarrow{e'_{i+1}} q'_{i+1}\) has an admissible run \(\pi^i\) such that \(\sum_{i=0}^{n-1} WT_{\pi^i} > 0\). This can be done also in NP, because \(n\) must be less than or equal to \(|Q|^2\).

**Proposition 3.8:** In \(CC_A(A_D^f, A_D^f)\), whether a transition is faulty, whether a transition is positive, whether a cycle is simple is possible, can be verified in NP in the size of \(A_D^f\).

**Definition 3.9:** Given \(k \in D\), in \(A_P\), a state \(q\) is called \(k\)-crucial (resp., anti-\(k\)-crucial) if there exists an unobservable cycle \(q \to q =: \pi\) such that \(WT_{\pi} > k\) (resp., \(WT_{\pi} < k\)). Such a cycle is called a \(k\)-crucial cycle (resp., \(anti-k\)-crucial cycle). A state \(q\) is called eventually \(k\)-crucial if either \(q\) is \(k\)-crucial or some \(k\)-crucial state \(q'\) is reachable from \(q\) through an unobservable path.

**Remark:** When \(D\) is polynomial, if a state is \(1\)-crucial, then it is \(k\)-crucial for any \(k \in D\) greater than 1, because a cycle can be repeated arbitrarily often.

For \(A_D^f\), we next show that all 0-crucial states can be computed in time polynomial in the size of \(A_D^f\): (1) Compute all reachable unobservable transitions of \(A_D^f\), denote the obtained subautomaton by \(Acc(A_D^f)\), which is considered as a weighted directed graph \((Q, V, A)\). (2) Compute all strongly connected components of \((Q, V, A)\) by using Tarjan algorithm, which takes time linear in the size of \((Q, V, A)\). (3) Choose a vertex \(q\) of \((Q, V, A)\) and the strongly connected component \(SCC_q\) containing \(q\). In \(SCC_q\), replace the weight \(w\) of any transition by \(-w\), denote the currently updated \(SCC_q\) by \(SCC_{2q}\). Then \(q\) is 0-crucial if and only if in \(SCC_{2q}\) there is a cycle with negative weight. One can use Bellman-Ford algorithm [29, Chap. 24] to check whether there is a cycle with negative weight reachable from \(q\) in time \(O(|V||A|)\). Similarly, all anti-0-crucial states can also be computed in polynomial time.

**Proposition 3.10:** In \(A_D^f\), whether a state is 0-crucial (resp., anti-0-crucial) can be verified in time polynomial in the size
of $\mathcal{A}^D$.

Furthermore, we need one property of $CC_A^\omega(\mathcal{A}_P^D, \mathcal{A}_n^D)$ in order to characterize $E_f$-diagnosability.

**Proposition 3.11:** Consider a labeled max-plus automaton $\mathcal{A}^D$. In the corresponding $CC_A^\omega(\mathcal{A}_P^D, \mathcal{A}_n^D)$, for every run

$$q_0' \overset{q'_1}{\rightarrow} \cdots \overset{q'_n}{\rightarrow} q_n',$$

where $n \in \mathbb{Z}_+$, $q'_1, \ldots, q'_n \in (E_{uo})^+$, there exists a run

$$q_0' \overset{q'_1}{\rightarrow} q'_1 \overset{q'_2}{\rightarrow} q'_n$$

such that $q'_1 \in (E_{uo} \times \{\epsilon\})^*, q'_2 \in (\{\epsilon\} \times (E_{uo} \setminus E_f))^*$, $q'_0(R) = \hat{q}_1^1(R)$, $\hat{q}_1^1(L) = q'_n(L)$, and the left (resp., right) component of (16) is the same as the left (resp., right) component of (17).

**Proof** One sees in $CC_A^\omega(\mathcal{A}_P^D, \mathcal{A}_n^D)$, all runs are unobservable. Then for every run $r$, we can swap any two consecutive transitions whose events have $\epsilon$ components in different positions but do not change the components of $r$. Without loss of generality, we consider the following run

$$(q_1, q_2) \overset{(e, q_1, q_2)}{\rightarrow} (q_3, q_2) \overset{(e, q_3, q_2)}{\rightarrow} (q_4, q_2),$$

and then change it as follows:

$$(q_1, q_2) \overset{(e, q_3, q_2)}{\rightarrow} (q_3, q_2) \overset{(e, q_4, q_2)}{\rightarrow} (q_5, q_2),$$

that is, in (19a), $(e_1, e_2, e_3, e_4, e_5, e_6) \in (E_{uo} \times \{\epsilon\})^*$, in (19b), $(e_1, e_2, e_3, e_4, e_5) \in (\{\epsilon\} \times (E_{uo} \setminus E_f))^*$, and then the left (resp., right) component of (18) is the same as the left (resp., right) component of (19). \qed

**Example 3:** Reconsider the automaton $\mathcal{A}^D_{\mathcal{N}_n}$ in Example 1 (shown in Fig. 1). Its faulty subautomaton $\mathcal{A}^D_{\mathcal{N}_f}$ and normal subautomaton $\mathcal{A}^D_{\mathcal{N}_n}$ are shown in Fig. 3. Its concurrent composition $CC_A(\mathcal{A}_P^D, \mathcal{A}_n^D)$ is shown in Fig. 4.

Fig. 4. $CC_A(\mathcal{A}^D, \mathcal{A}^D)$ corresponding to automaton $\mathcal{A}^D_{\mathcal{N}_n}$ in Fig. 1.

C. A sufficient and necessary condition for $E_f$-diagnosability of $\mathcal{A}^D$

In this subsection, for a labeled max-plus automaton $\mathcal{A}^D$ over a progressive dioid $D$, we use the corresponding concurrent composition $CC_A(\mathcal{A}_P^D, \mathcal{A}_n^D)$ to give a sufficient and necessary condition for negation of its $E_f$-diagnosability (as in Definition 3.3). By Lemma 3.2, we assume $\mathcal{A}^D$ is stuck-free without loss of generality.

**Theorem 3.12:** Consider a labeled max-plus automaton $\mathcal{A}^D$ (7), where $D$ is progressive, $\mathcal{A}^D$ is not $E_f$-diagnosable if and only if in the corresponding concurrent composition $CC_A(\mathcal{A}_P^D, \mathcal{A}_n^D)$ (14), at least one of the following four conditions holds.

(iv) There exists a path

$$q'_0 \overset{q'_1}{\rightarrow} q'_1 \overset{q'_2}{\rightarrow} q'_2 \overset{q'_3}{\rightarrow} q'_3,$$

where $q'_0 \in Q_0, q'_1, q'_3 \in (E'_o)^*, e'_2 \in E'_f, q'_1 \stackrel{q'_2}{\rightarrow} q'_2$ is faulty, and $q'_3$ belongs to a positive transition cycle.

(v) There exists a path

$$q'_0 \overset{q'_1}{\rightarrow} q'_1 \overset{q'_2}{\rightarrow} q'_2 \overset{q'_3}{\rightarrow} q'_3,$$

where $q'_0 \in Q_0, q'_1, q'_3 \in (E'_o)^*, e'_2 \in E'_f, q'_1 \stackrel{q'_2}{\rightarrow} q'_2$ is faulty, $q'_3(L)$ is eventually 1-crucial in $\mathcal{A}^D$, and $q'_3(R)$ is eventually 1-crucial in $\mathcal{A}^D$.

(vi) There exists a path

$$q'_0 \overset{q'_1}{\rightarrow} q'_1 \overset{q'_2}{\rightarrow} q'_2 \overset{q'_3}{\rightarrow} q'_3,$$

where $q'_0 \in Q_0, q'_1 \in (E'_o)^*, e'_2 \in (E'_o \setminus \{\epsilon\})^*, e'_3 \in E_f \times \{\epsilon\}$, $q'_3(L)$ is eventually 1-crucial in $\mathcal{A}^D$, and $q'_3(R)$ is eventually 1-crucial in $\mathcal{A}^D$.

(vii) There exists a path

$$q'_0 \overset{q'_1}{\rightarrow} q'_1 \overset{q'_2}{\rightarrow} q'_2 \overset{q'_3}{\rightarrow} q'_3,$$

where $q'_0 \in Q_0, q'_1 \in (E'_o)^*, e'_2 \in (E'_o \setminus \{\epsilon\})^*, e'_3 \in E_f \times \{\epsilon\}$, $q'_3(L)$ is eventually 1-crucial in $\mathcal{A}^D$, and $q'_3(R)$ is eventually 1-crucial in $\mathcal{A}^D$.

**Proof** The proof of this result is put into Appendix in order not to delay the statement at this point. \qed
Because dioid $\mathbb{Q}$ is progressive, by Theorem 3.12 we directly have the following result.

**Theorem 3.13:** A labeled max-plus automaton $A_{\mathbb{Q}}$ is not $E_f$-diagnosable if and only if in the corresponding concurrent composition $CC_A(A_{\mathbb{Q}}, A_{\mathbb{P}})$, at least one of the following four conditions holds.

(viii) There exists a path

$$q_0' \xrightarrow{e_1} q_1' \xrightarrow{e_2} q_2' \xrightarrow{e_3} q_3',$$

where $q_0' \in Q_0$, $s_1, s_3 \in (E_o')^*$, $e_1, e_3 \in E_o'$, $q_1'$ is faulty, and $q_3'$ belongs to a positive transition cycle.

(ix) There exists a path

$$q_0' \xrightarrow{e_1} q_1' \xrightarrow{e_2} q_2' \xrightarrow{e_3} q_3',$$

where $q_0' \in Q_0$, $s_2, s_3 \in (E_o')^*$, $e_1, e_3 \in E_f \times \{\epsilon\}$, $q_3'(L)$ is eventually 0-crucial in $A_{\mathbb{P}}$, and $q_3'(R)$ is eventually 0-crucial in $A_{\mathbb{Q}}$.

(x) There exists a path

$$q_0' \xrightarrow{e_1} q_1' \xrightarrow{e_2} q_2' \xrightarrow{e_3} q_3',$$

where $q_0' \in Q_0$, $s_2 \in (E_o')^*$, $s_2' \in (E_o')^*$, $e_3 \in E_f \times \{\epsilon\}$, $q_3'(L)$ is eventually 0-crucial in $A_{\mathbb{P}}$, and some state in

$$q_3'(L) : q_3'(L) \xrightarrow{e_3} q_3(L)$$

is anti-0-crucial in $A_{\mathbb{Q}}$.

**Corollary 3.14:** A labeled max-plus automaton $A_{\mathbb{Q}}$ is not $E_f$-diagnosable if and only if in the corresponding concurrent composition $CC_A(A_{\mathbb{Q}}, A_{\mathbb{P}})$, at least one of (viii), (ix), and (x) adapted to $A_{\mathbb{Q}}$ to holds (xi) must not hold because $A_{\mathbb{Q}}$ contains no transition with negative weight.

**Example 4:** Reconsider the automaton $A_{\mathbb{Q}}$ in Example 1 (shown in Fig. 1). In its concurrent composition $CC_A(A_{\mathbb{Q}}, A_{\mathbb{P}})$ (in Fig. 4), the observable transition $(q_0, q_0) \xrightarrow{(a,a)} (q_3, q_4)$ is faulty, because it has two admissible paths $q_0 \xrightarrow{a} q_1 \xrightarrow{a} q_3$ and $q_0 \xrightarrow{a} q_2 \xrightarrow{a} q_4$ both with weight 4; moreover, the observable self-loop $(q_3, q_4) \xrightarrow{(a,a)} (q_3, q_4)$ is positive, because it has two admissible paths $q_3 \xrightarrow{a} q_3$ and $q_4 \xrightarrow{a} q_4$ both with positive weight 1. Hence (viii) of Theorem 3.13 is satisfied, $A_{\mathbb{Q}}$ is not $\{f\}$-diagnosable, which is consistent with the result obtained in Example 2, (ix) is not satisfied. (ix) is satisfied, because in path $(q_0, q_0) \xrightarrow{(e_1,e_3)} (q_1, q_0)$, $q_1$ is 0-crucial in $A_{\mathbb{Q}}$ (because of the unobservable self-loop on $q_1$ with positive weight) and $q_0$ is eventually 0-crucial in $A_{\mathbb{Q}}$ (because of the unobservable path $q_0 \xrightarrow{u} q_2 \xrightarrow{u} q_2$). (x) is not satisfied.

Next we give an example for which only (xi) of Theorem 3.13 is satisfied.

**Example 5:** Consider a second stuck-free labeled max-plus automaton $A_{\mathbb{Q}}$ shown in Fig. 5. One easily sees that in $CC_A(A_{\mathbb{Q}}, A_{\mathbb{P}})$, there is no observable transition. Then neither (viii) nor (ix) is satisfied. (x) is not satisfied either, because in $A_{\mathbb{Q}}$, there is no reachable eventually 0-crucial state. (xi) is satisfied, because in path $q_0 \xrightarrow{u} q_1 \xrightarrow{u} q_1 \xrightarrow{f} q_2$, $q_1 \xrightarrow{u} q_1$ is an anti-0-crucial cycle, $q_2$ is 0-crucial. Hence $A_{\mathbb{Q}}$ is not $\{f\}$-diagnosable. Moreover, choose paths

$$q_0 \xrightarrow{u} q_1 \xrightarrow{u} q_1 \xrightarrow{f} q_2 =: \pi_t,$$

where $t \in \mathbb{Z}_+$. Then one has

$$\ell(\tau(\pi_t)) = \ell(\tau(\pi_t')) = \epsilon,$$

where $\pi_t = t + 1 > t$, $\pi_t' = 0 > WT_\pi t + t = -2$.

By Proposition 3.3, one also has $A_{\mathbb{Q}}$ is not $\{f\}$-diagnosable.

**D. The complexity of verifying diagnosability of labeled max-plus automaton $A_{\mathbb{Q}}$**

We give the following complexity result on verifying $E_f$-diagnosability of $A_{\mathbb{Q}}$.

**Theorem 3.15:** The problem of verifying $E_f$-diagnosability of a labeled max-plus automaton $A_{\mathbb{Q}}$ is coNP-complete, where coNP-hardness even holds for deterministic, deadlock-free, and divergence-free $A_{\mathbb{Q}}$.

**Proof** “coNP-membership”:

Recall that the concurrent composition $CC_A(A_{\mathbb{Q}}, A_{\mathbb{P}})$ can be computed in NP (Theorem 3.6).

In (viii), by definition, we can assume $q_3$ belongs to a positive simple transition cycle without loss of generality. By Proposition 3.3, in $CC_A(A_{\mathbb{Q}}, A_{\mathbb{P}})$, whether an observable transition is faulty can be verified in NP, whether a simple observable transition cycle is positive can also be verified in NP, so (viii) can be verified in NP.

By Proposition 3.10, whether a state of $A_{\mathbb{Q}}$ is 0-crucial (resp., anti-0-crucial) can be verified in polynomial time. Hence in (ix), (x), and (xi), whether $q_3(L)$ is eventually 0-crucial in $A_{\mathbb{Q}}$, whether $q_3(R)$ is eventually 0-crucial in $A_{\mathbb{Q}}$, and whether some state in $q_3(L)$ $\xrightarrow{u}$ $q_3(L)$ is anti-0-crucial in $A_{\mathbb{Q}}$ can be verified in polynomial time. Hence (ix), (x), and (xi) can be verified in NP.

“coNP-hardness”: 

```
We reduce the NP-complete SS problem (Problem 2) to negation of $E_f$-diagnosability of $A_{\mathcal{N}_0}^{\mathcal{N}_0}$ in polynomial time.

Given positive integers $n_1, \ldots, n_m$, and $N$, we next construct in polynomial time a labeled max-plus automaton $A_{\mathcal{N}_0}^{\mathcal{N}_0}$ as illustrated in Fig. 6. $q_0$ is the unique initial state and has initial time delay 0. Events $u, u_1, u_2$, and $e_f$ are unobservable. Events $a$ and $b$ are observable, $\ell(a) = a$ and $\ell(b) = b$. Only $e_f$ is faulty. For all $i \in [0, m - 1]$, there exist two unobservable transitions $q_i \xrightarrow{u_{i+1/n_i + 1}} q_{i+1}$ and $q_i \xrightarrow{u_{2/n_i + 2}} q_{i+1}$. The other unobservable transitions are $q_i \xrightarrow{e_f^1} q_{i+1}$ and $q_i \xrightarrow{e_f^2} q_{i+2}$. The observable transitions are $q_i \xrightarrow{a^1} q_{i+1}$ and $q_i \xrightarrow{b^1} q_{i+2}$, and two self-loops $q_m \xrightarrow{a^2} q_m$ and $q_m \xrightarrow{b^2} q_m$. Denote $\{u, u_1, u_2, e_f, a, b\} =: E$. Apparently $A_{\mathcal{N}_0}^{\mathcal{N}_0}$ is deterministic, deadlock-free, and divergence-free (having no reachable unobservable cycle).

Fig. 6. Sketch of the reduction in the proof of Theorem 3.15.

Suppose there exists $I \subset [1, m]$ such that $N = \sum_{i \in I} n_i$. Then there is an unobservable path $\pi \in q_0 \leadsto q_m$ whose weight is equal to $N$. Then for an arbitrary $t \in \mathbb{N}_0$, we choose

\[
\begin{align*}
\pi_t &= \pi \xrightarrow{a} q_{m+1} \xrightarrow{e_f^1} q_{m+2}, \\
\pi_t' &= q_1 \xrightarrow{b} q_{m+2}^2, \\
\pi_t'' &= q_0 \xrightarrow{a} q_{m+1} \xrightarrow{u} q_{m+2}^2 \xrightarrow{b} q_{m+2}^2.
\end{align*}
\]

Then we have

$e_f \notin \{u \cup \{a, b\}^*\}$,

$W T_{\pi_t} = t$,

$W T_{\pi_t'} = N + 2 + t = W T_{\pi_t} + t$,

$\ell(\tau(\pi_t')) = \ell(\tau(\pi_t'')) = (a, N + 1)(b, N + 3) \ldots (b, N + t + 2)$.

By definition, $A_{\mathcal{N}_0}^{\mathcal{N}_0}$ is not $\{e_f\}$-diagnosable. Assume for all $I \subset [1, m]$, $N \neq \sum_{i \in I} n_i$. Choose $t = 1$, and choose an arbitrary path starting from $q_0$ whose last event is faulty, then the path must be of the form

$\pi \xrightarrow{a} q_{m+1} \xrightarrow{e_f} q_{m+2}$,

where $\pi \in q_0 \leadsto q_m$. We have $W T_{\pi} \neq N$. Choose an arbitrary continuation $q_{m+2} \xrightarrow{b} q_{m+2}^2$, with $t' \geq t$, then if we observe $\ell\left( \tau\left( \pi \xrightarrow{a} q_{m+1} \xrightarrow{e_f} q_{m+2} \xrightarrow{b} q_{m+2}^2 \right) \right)$, we know that $A_{\mathcal{N}_0}^{\mathcal{N}_0}$ must be in state $q_{m+2}^2$. Hence $e_f$ has occurred. That is, $A_{\mathcal{N}_0}^{\mathcal{N}_0}$ is $\{e_f\}$-diagnosable.

IV. CONCLUSION

In this paper, we formulated a notion of diagnosability for labeled max-plus automata over a subclass of dioids called progressives which could represent time elapsing. We gave a notion of concurrent composition for such automata and used the notion to give a sufficient and necessary condition for diagnosability. We also proved that for the dioid $(\mathbb{Q} \cup \{-\infty\}, \max, +, -\infty, 0)$ (which is progressive), a concurrent composition can be computed in NP and verifying diagnosability is coNP-complete, where coNP-hardness even holds for deterministic, deadlock-free, and divergence-free automata. Note that particularly when the weights of the transitions of the considered automata are nonnegative rational numbers, the automata become a subclass of (labeled) timed automata. Recall that for timed automata, the diagnosability verification problem is PSPACE-complete [20], hence in this paper a subclass of timed automata for which the diagnosability problem belongs to coNP was found.

such that
\[ WT(\tilde{q}_i(R)) \xrightarrow{\ell} q_i'(R) \xrightarrow{\ell} q_i''(R) \xrightarrow{\ell} q_i'''(R) =: \pi_{i''}, \]

one then has \( \ell(\tau(\pi_{i''})) = \ell(\tau(\pi_i')) \), \( E_f \notin \tilde{s}_i \tilde{s}_2 \tilde{s}_3 \tilde{s}(\tilde{s}_2)2n \), \( WT_{\pi_1} = WT(q_i'(L) \xrightarrow{\ell} q_i''(L)) \otimes 2n \geq l^n > t \), and \( WT_{\pi_1} = WT_{\pi_1} \otimes WT_{\pi_1} > WT_{\pi_1} \otimes \emptyset \) (by \( WT_{\pi_1} \neq 0 \) and Lemma 2.5). Then By Proposition 3.4, \( A^D \) is not \( E_f \)-diagnosable.

Assume (v) holds. Then there exist unobservable paths
\[ q_i'(L) \xrightarrow{\ell} q_i''(L) \xrightarrow{\ell} q_i'''(L) \xrightarrow{\ell} q_i''''(L) \]

such that
\[ s_4 \in (E_{uo})^*, s_5 \in (E_{uo})^+, s_6 \in (E_{uo} \setminus E_f)^*, s_7 \in (E_{uo} \setminus E_f)^+ \], \( \ell(s_4) = l_1 > 1 \), and \( WT(q_4 \xrightarrow{\ell} q_5) =: l_2 > 1 \).

By (21), in \( A^D \) there exist paths
\[ q_i'(L) \xrightarrow{\ell} q_i''(L) \xrightarrow{\ell} q_i'''(L) \xrightarrow{\ell} q_i''''(L) \xrightarrow{\ell} q_i'''''(L) =: \pi_i', \]

such that
\[ s_i \in E_{uo}^*, s_i \in (E \setminus E_f)^* (E_{uo} \setminus E_f) \] for \( i = 1, 3, 4 \), \( s_2 \in (E_{uo})^* E_o, s_2 \in (E_{uo} \setminus E_f)^* (E_{uo} \setminus E_f) \), \( \ell(s_2) = \ell(s_2) \), \( \ell(s_2) = \ell(s_3) \), \( s_3 \in (E_{uo})^* E_o \), \( s_3 \in (E_{uo} \setminus E_f)^* (E_{uo} \setminus E_f) \).

\[ \ell(\tau(q_i''''(L) \xrightarrow{\ell} q_i'''(L))) = \ell(\tau(q_i'''(L) \xrightarrow{\ell} q_i''''(L))) \]

for all \( i \in [1, 3] \), \( \ell(\tau(q_i'(L) \xrightarrow{\ell} q_i''(L))) = \ell(\tau(q_i''(L) \xrightarrow{\ell} q_i'''(L))) \), \( \ell(\tau(q_i''''(L) \xrightarrow{\ell} q_i'''(L))) = \ell(\tau(q_i'''(L) \xrightarrow{\ell} q_i''''(L))) \), \( \ell(\tau(q_i''''(L) \xrightarrow{\ell} q_i'''(L))) = \ell(\tau(q_i'''(L) \xrightarrow{\ell} q_i''''(L))) \), \( \ell(\tau(q_i''''(L) \xrightarrow{\ell} q_i'''(L))) = \ell(\tau(q_i'''(L) \xrightarrow{\ell} q_i''''(L))) \).

One then has \( E_f \subset \tilde{s}_2, E_f \notin \tilde{s}_2 \tilde{s}_2 \tilde{s}_3 \tilde{s}(\tilde{s}_2)2n \), \( \ell(\tau(\pi_{i''})) = \ell(\tau(\pi_i')) \), \( WT_{\pi_1} = WT(q_i'(L) \xrightarrow{\ell} q_i''(L)) \otimes 2n \geq l^n > t \), and \( WT_{\pi_1} = WT_{\pi_1} \otimes WT_{\pi_1} > WT_{\pi_1} \otimes \emptyset \) (by Lemma 2.5).

Then also by Proposition 3.4, \( A^D \) is not \( E_f \)-diagnosable.

Assume (vi) holds. Then similarly to (v), there also exist unobservable paths in \( A^D \) as in (28).

By (22), in \( A^D \) there exist paths
\[ q_i'(L) \xrightarrow{\ell} q_i''(L) \xrightarrow{\ell} q_i'''(L) \xrightarrow{\ell} q_i''''(L) \]

such that
\[ s_1 \in E_{uo}^*, s_1 \in (E \setminus E_f)^* (E_{uo} \setminus E_f) \]
\[ \ell(s_1) = \ell(s_1') = \ell(s_1''), \]
\[ \ell(\tau(q_0(L), \overline{q}_1(L))) = \ell(\tau(q_0'(R), \overline{q}_1'(R))), \]
\[ \text{WT}(q_0'(L) \overline{\rightarrow} q_1'(L)) = \text{WT}(q_0'(R) \overline{\rightarrow} q_1'(R)), \]
\[ q_2'(R) = q_3'(R), \quad (e_f, e) = e_3'. \]

Let \( t \in D \) be such that \( t > 1 \). Choose a sufficiently large \( n \in N_0 \) such that \((l_1)^n > t\) and \( \text{WT}(q_0'(L) \overline{\rightarrow} q_4) \otimes\ (l_1)^n \). Then choose sufficiently large \( m \in N_0 \) such that \( \text{WT}(q_0'(L) \overline{\rightarrow} q_4) \otimes\ (l_1)^n \otimes\ (l_2)^n \).

\[ q_0'(L) \overline{\rightarrow} q_1'(L) \overline{\rightarrow} q_2'(L) \overline{\rightarrow} q_3'(L) = \pi_t, \]
\[ q_0'(R) \overline{\rightarrow} q_1'(R) \overline{\rightarrow} q_2'(R) \overline{\rightarrow} q_3'(R), \]
\[ q_0'(R) \overline{\rightarrow} q_1'(R) \overline{\rightarrow} q_2'(L) \overline{\rightarrow} q_3'(L) = \pi_{t''}. \]

One then has \( E_f \neq \pi_1 s_2'(R) s_0 s_7' \), \( \ell(\pi(t_1, \pi_t')) = \ell(\tau(q_0'(L) \overline{\rightarrow} q_1(L))), \) \( \text{WT}_{\pi_t'} = \text{WT}(q_0'(L) \overline{\rightarrow} q_4) \otimes\ (l_1)^n \geq t, \) \( \text{WT}(q_0'(L) \overline{\rightarrow} q_4) \otimes\ (l_2)^n \geq t, \) \( \text{WT}_{\pi_t''} = \text{WT}(q_0'(L) \overline{\rightarrow} q_4) \otimes\ (l_2)^n \). Also by Proposition 3.4, \( A^P \) is not \( E_f \)-diagonasol.

Assume (vi) holds. Then there exist unparsable paths
\[ q_0'(L) \overline{\rightarrow} q_1'(L) \overline{\rightarrow} q_2'(L) \overline{\rightarrow} q_3'(L) \]
\[ q_0'(R) \overline{\rightarrow} q_1'(R) \overline{\rightarrow} q_2'(R) \overline{\rightarrow} q_3'(R) \]
such that \( q_0' \) appears in \( q_1'(L) \overline{\rightarrow} q_2'(L) \), \( s_4 \in (E_0^o)^{s_4}, \)
\[ s_5, s_6 \in (E_0^o)^{s_6}, \text{WT}(q_4 \overline{\rightarrow} q_4) = : l_1 > 1, \text{WT}(q_5 \overline{\rightarrow} q_5) = \).

By (23), in \( A^P \) there exist paths
\[ q_0'(L) \overline{\rightarrow} q_1'(L) \overline{\rightarrow} q_2'(L) \overline{\rightarrow} q_3'(L) \]
\[ q_0'(R) \overline{\rightarrow} q_1'(R) \overline{\rightarrow} q_2'(R) \overline{\rightarrow} q_3'(R) \]
such that
\[ \pi_t = \pi_t' = \pi_t'' \]
\[ \pi_t' \]
\[ \pi_t'' \]
\[ \pi_t''' \]
\[ \pi_t'''' \]
\[ \pi_t''' = \pi_t'''' \]
\[ \pi_t'''' \]
\[ \pi_t'''' \]
\[ \pi_t''' = \pi_t'''' \]

Assume that \( A^P \) is not \( E_f \)-diagonasol. We choose a sufficiently large \( 1 < t \in D \). This can be done because there is an element \( t' \in D \) greater than 1 and \( t < t' < (t')^2 < (t')^3 < \cdots \)
(by Corollary 2.8). By Proposition 3.4, there exist paths
\[ q_0 = q_0^1 \overline{\rightarrow} q_1', \quad \pi = \pi', \quad \pi' = \pi'' = q_0^2 \overline{\rightarrow} q_2', \]

By definition of \( CC_\Lambda(A^P, A^P) \), the two paths \( \pi_t, \pi_t' \) and \( \pi_t'' \) generate a run \( \pi'' \) of \( CC_\Lambda(A^P, A^P) \) consisting of a sequence of observable transitions followed by a sequence of unobservable transitions. Note that particularly, \( \pi'' \) may contain only observable transitions or only unobservable transitions. Hence \( \pi_t, \pi_t' \) and \( \pi_t'' \) can be rewritten as
\[ q_0 = q_0^1 \overline{\rightarrow} \ldots \overline{\rightarrow} q_n \overline{\rightarrow} q_{n+1}, \]
\[ \hat{q}_0 = \hat{q}_0^1 \overline{\rightarrow} \ldots \overline{\rightarrow} \hat{q}_n \overline{\rightarrow} \hat{q}_{n+1}, \]

respectively, where \( q_0 = q_0^1, q_{n+1} = q_2, q_0 = q_0^2, q_{n+1} = q_2^2, n \in N_0 \), for all \( i \in \{1, n\} \), \( \tilde{s}_i \in (E_0^o)^{E_0}, \tilde{s}_i \in (E_0^o)^{E_0}, \tilde{s}_i \in (E_0^o)^{E_0}, \)
\[ \text{WT}(\tilde{q}_i \overline{\rightarrow} \tilde{q}_i) = \text{WT}(\tilde{q}_i \overline{\rightarrow} \tilde{q}_i), \]

and
\[ \pi'' = (\tilde{q}_0, \hat{q}_0^1 \overline{\rightarrow} (\tilde{q}_n, \hat{q}_n^1 \overline{\rightarrow} (\hat{q}_{n+1}, \hat{q}_{n+1}), \]

and
\[ \pi'' = (\tilde{q}_0, \hat{q}_0^1 \overline{\rightarrow} (\tilde{q}_n, \hat{q}_n^1 \overline{\rightarrow} (\hat{q}_{n+1}, \hat{q}_{n+1}), \]

and
where \( s'_{n+1} \in (E_{\omega})^* \), \( s'_{n+1}(L) = s_{n+1}, s'_{n+1}(R) = s_{n+1} \), for every \( i \in [1, n] \), \((q_{i-1}, \hat{q}_{i-1}) \to \frac{s_{n+1}}{(\text{last}(s_{n+1}), \text{last}(s_{n+1}))} \to (q_{i}, \hat{q}_{i}) \) is an observable transition, \((q_n, \hat{q}_n) \to \frac{s_{n+1}}{(q_{n+1}, \hat{q}_{n+1})} \) is a sequence of unobservable transitions.

The subsequent argument is divided into four cases.

(a) Case \( s_1 \ldots \hat{s}_n = s \):

In this case, last \((s_n) \in E_f \), \( \pi_t = \hat{q}_0 \to \ldots \to \hat{q}_n \), \( \pi'_t = \hat{q}_0 \to \ldots \to \hat{q}_n \), \( \text{WT}(\hat{q}_0 \to \ldots \to \hat{q}_n) > \text{WT}(\hat{q}_0 \to \ldots \to \hat{q}_n) \), \( \text{WT}(\pi'_t \to t) = \text{WT}(\pi_t \to t) \). Then we have \( \text{WT}(\hat{q}_0 \to \ldots \to \hat{q}_n) \geq \text{WT}(\pi_t \to t) \). Therefore, \( \text{WT}(\hat{q}_0 \to \ldots \to \hat{q}_n) \geq t \) because a path always has nonzero weight and \( D \) is cancellative. Rank that \( \pi_t \) is sufficiently large. Divide \( \hat{q}_n \to \hat{q}_{n+1} \) to paths \( \pi_1 \to \pi_m \) such that last \((\pi_1) = \text{init}(\pi_1) \) for all \( i \in [1, m-1] \), where \( \pi_1 \) is the shortest prefix of \( \hat{q}_n \to \hat{q}_{n+1} \) having weight greater than 1, \( \pi_2 \) is the shortest prefix of \( \hat{q}_n \to \hat{q}_{n+1} \) having weight greater than 1, \( \ldots \), \( \pi_{m-1} \) is the shortest prefix of \( \hat{q}_n \to \hat{q}_{n+1} \). Hence \( (\pi_{m-1}) \to (\pi_{m-1}) \) holds. Using argument similar as above, one also has at least one \( s'_{n+1} \) is the shortest sequence in \( \mathcal{A}_{\pi} \), \( \pi_{m-1} \to \pi_{m+1} \) is a suffix of \( s', s_{m+1}(\pi_{m-1}) \neq \epsilon \).

(b) Case \( s_1 \ldots \hat{s}_n \subseteq s \):

In this case, denote \( \pi_t := \hat{q}_0 \to \ldots \to \hat{q}_n \). We have \( \text{WT}(\hat{q}_n) > \text{WT}(\hat{q}_n) \), \( \text{WT}(\hat{q}_0 \to \ldots \to \hat{q}_n) = \text{WT}(\hat{q}_0 \to \ldots \to \hat{q}_n) \), \( \text{WT}(\pi_t) \geq \text{WT}(\pi_t \to t) \). The argument as in (a), we know last \((\pi'_t) \) is eventually 1-crucial in \( \mathcal{A}_{\pi} \). By Lemma 2.5, we have \( \text{WT}(\hat{q}_n \to \hat{q}_{n+1}) \geq \text{WT}(\pi_t \to t) \).

- Assume \( \hat{q}_n \to \hat{q}_{n+1} \) has a prefix \( \pi'_t \) such that \( \text{WT}(\hat{q}_n \to \hat{q}_{n+1}) \leq \text{WT}(\hat{q}_n \to \hat{q}_{n+1}) \). Then \( \text{WT}(\hat{q}_n \to \hat{q}_{n+1}) \geq \text{WT}(\pi_t \to t) \). By using the argument as in (a), we know \( \pi'_t \) is eventually 1-crucial in \( \mathcal{A}_{\pi} \). That is, (vi) holds.

- Assume \( \hat{q}_n \to \hat{q}_{n+1} \) has no prefix with weight no greater than \( \text{WT}(\pi_t) \). Then \( \text{WT}(\pi_t) < 1 \). If \( \hat{q}_n \to \hat{q}_{n+1} \) contains a 1-crucial cycle in \( \mathcal{A}_{\pi} \), then (vi) holds; otherwise, we must have \( \text{WT}(\pi_t) \) is sufficiently small, then also using the argument as in (a) we have \( \pi'_t \) contains an anti-1-crucial cycle in \( \mathcal{A}_{\pi} \), i.e., (vii) holds.

(c) Case \( s \subseteq s_1 \ldots s_n \) and \( s_{n+1} = \epsilon \):

Choose \( m \in [1, n] \) such that \( s_1 \ldots s_{m-1} \subseteq s \subseteq s_1 \ldots s_m \).

- Assume \( s_1 \ldots s_{m-1} \subseteq s \).

If there exists \( l \in [m, n] \) such that \( \text{WT}(\hat{q}_{l-1} \to \hat{q}_l) \) is sufficiently large, then \( \hat{q}_{l-1} \to \hat{q}_l \) contains a 1-crucial cycle in \( \mathcal{A}_{\pi} \), \( \hat{q}_{l-1} \to \hat{q}_l \) contains a 1-crucial cycle in \( \mathcal{A}_{\pi} \), then (v) holds. Otherwise if such \( l \) does not exist, then the weights of \( \hat{q}_{m-1} \to \hat{q}_m \), \( \ldots \), \( \hat{q}_n \) cannot be arbitrarily large. Because \( t \) is sufficiently large and \( \text{WT}(\hat{q}_{m-1} \to \hat{q}_m), \ldots, \hat{q}_n, \) by using the argument as in (a), in \( (\hat{q}_{m-1} \to \hat{q}_m) \to (\hat{q}_n) \) there exists a positive cycle. Hence (iv) holds.

- Assume \( s_1 \ldots s_{m-1} \subseteq s \). From \( \hat{q}_{m-1} \to \hat{q}_m \) and \( \hat{q}_m \to \hat{q}_{m+1} \), by Proposition 3.11, we obtain an unobservable sequence \( (\hat{q}_{m-1} \to \hat{q}_m) \to (\hat{q}_m \to \hat{q}_{m+1}) \). Then (v) holds, and the \( s'_{m+1} \) is (21) in equal to \( \epsilon \).

(d) Case \( s \neq s_1 \ldots s_n \) and \( s_{n+1} = \epsilon \):

Using argument similar as above, one also has at least one of (iv), (vi), and (vii) holds. This finishes the proof.
