Abstract Replication studies are increasingly conducted to assess credibility of scientific findings. Most of these replication attempts target studies with a superiority design, but there is a lack of methodology regarding the analysis of replication studies with alternative types of designs. In order to fill this gap, we adapt three approaches used for superiority settings to non-inferiority and equivalence designs: the two-trials rule, the sceptical \( p \)-value approach and the meta-analysis criterion. While the adaptation to the non-inferiority design is relatively straightforward, the equivalence design requires more effort. We propose to use the ‘two one-sided test’ (TOST) procedure and tailor it to the replication setting. In addition, we formulate the different criteria in terms of a ‘success interval’ for the relative effect size (replication to original). The properties of the different approaches are studied in detail. In particular, the two-trials rule does not penalize replication effect estimates very close to the margin for large sample sizes. The meta-analysis criterion is convenient as it combines the two estimates into one, but can lead to replication success in odd situations. Finally, the sceptical \( p \)-value approach seems well-suited as it penalizes a too large increase of the replication effect estimate as compared to the original one, while taking into account the direction of the latter in the calculation of the success interval.

1 Introduction

Replicability of scientific findings is the gold standard to assess their credibility. Recent years have witnessed an increased interest in large-scale replication projects, aiming to reproduce the results found in an
original study in one or several replication studies. Various empirical domains of science are involved in these replication efforts: psychology [Open Science Collaboration, 2015], social sciences [Camerer et al., 2016], economics [Camerer et al., 2018] and more recently cancer biology [Errington et al., 2021], among others.

In the majority of these endeavors, original studies have a statistically significant effect estimate i.e. there is evidence, in the original study, against a point null hypothesis. A replication study is then conducted to confirm the initial result and a significant replication effect estimate in the same direction is generally interpreted as a successful replication. Requiring two statistically significant studies is analogous to the two-trials rule in drug development [FDA, 1998]. But the two-trials rule is not the only criterion for the assessment of replication success; many replication projects also consider other measures such as compatibility of the effect estimates from both studies and meta-analysis of these estimates. Furthermore, there is a growing body of literature on the design and analysis of such replication studies, and new methodology is emerging (e.g. in Anderson and Maxwell [2017], Bonett [2020], Held [2020], Hedges and Schauer [2021], Micheloud and Held [2022], Held et al. [2022]).

However, it might also happen that non-significant original studies are selected for replication. This was for example the case for 22 of the 158 effects (14%) in the Reproducibility Project Cancer Biology [RPCB, Errington et al., 2021], where non-significant effects were termed ‘null effects’. One criterion for replication success of an original null effect was a null effect in the replication study as well, i.e. a non-significant replication effect estimate. Another criterion was a combined null (non-significant) effect from a meta-analysis of both (original and replication) studies. However, interpreting a non-significant effect as null can be misleading, as the apparent null effect could in reality be caused by a low sample size, which, if increased, would render the same effect statistically significant. In fact, if the aim of the original (and subsequently the replication) study is to show that an effect is null, then another type of design needs to be used in both studies: an equivalence design.

Equivalence studies are conducted to show the opposite of superiority studies, namely that an effect \( \theta \) is sufficiently close to 0 that it can be considered negligible. Because it is impossible to accept a point hypothesis, an interval of equivalence \([-\delta; \delta]\) needs to be specified in the equivalence design [Serlin and Lapsley, 1985]. In clinical trials regulations, the International Conference on Harmonisation (ICH) E9 [ICH E9 Expert Working Group, 1999, p. 18] states that the margin \( \delta \) is ‘the largest difference that can be judged as being clinically acceptable and should be smaller than differences observed in superiority trials of the active comparator’. The composite hypotheses \( H_0 \) and \( H_1 \) can be decomposed into two one-sided hypotheses, namely

\[
H_0^- : \theta \leq -\delta \text{ vs. } H_1^- : \theta > -\delta
\] 

(1)
and

\[ H_0^+ : \theta \geq \delta \text{ vs. } H_1^+ : \theta < \delta. \] (2)

This decomposition is the basis of a widely used method in the assessment of equivalence known as the ‘two one-sided tests (TOST)’ procedure [Schuirmann, 1987]. Equivalence of the unknown effect \( \theta \) is declared if and only if both null hypotheses in (1) and (2) are rejected in favor of the alternative at the one-sided chosen nominal level of significance \( \alpha \). Equivalence designs have been used for many years now, especially in clinical trials and pharmacokinetics, and the methodology has been extensively discussed. Nevertheless, there has been little interest so far in situations where the original study has an equivalence design and the replication aims to confirm this equivalence.

The primary aim of this paper is to fill this gap and to present methodology to analyze equivalence replication studies. We will adapt approaches used in the replication of superiority studies to non-inferiority and equivalence designs. The aim of a non-inferiority study in clinical trials is to show that a new treatment or intervention is not ‘unacceptably worse’ than a standard treatment. This type of studies is common in real-world evidence replication studies of randomized controlled trials [Franklin et al., 2021]. Three analysis strategies are compared: the two-trials rule [FDA, 1998], which requires two significant findings, the sceptical \( p \)-value approach, which is a reverse-Bayes method developed by Held [2020], and the meta-analysis criterion. Compatibility of the effect estimates is not discussed as it does not take into account the non-inferiority/equivalence margin.

A common problem in superiority designs is that original findings are often inflated due to various biases [Ioannidis, 2008]. In contrast, replication findings usually do not suffer from such flaws. As a result, the shrinkage of the replication effect estimate from the original one can be substantial, and should be taken into account in the assessment of replication success. This has been described in detail in [Held, 2020] and Held et al. [2022] and will be outlined in Section 2. The same issue may appear in non-inferiority studies. In contrast, original studies with an equivalence design tend to produce effect estimates which are too close to 0, and one would like to penalize an increase (in absolute value) of the replication effect as compared to the original one. This will be described and discussed in Section 3.

The paper is structured as follows: Section 2 reviews some of the existing methodology for the analysis of replication studies of superiority and extends it to non-inferiority designs. In Section 3 the approaches discussed in Section 2 are adapted to equivalence designs and compared. Finally, some discussion is provided in Section 4. A study from the RPCB [Errington et al., 2021] is presented in Section 1.2 and will be used as a running example.
1.1 Statistical framework

In our framework the original and replication effect estimates \( \hat{\theta}_o \) and \( \hat{\theta}_r \) of the unknown effect \( \theta \) are assumed to be normally distributed with standard error \( \sigma_o \) and \( \sigma_r \), respectively. The squared standard errors can generally be expressed as \( \sigma^2_o = \kappa^2/n_o \) and \( \sigma^2_r = \kappa^2/n_r \) where \( \kappa^2 \) is some unit variance and \( n_o \) and \( n_r \) the original and replication sample sizes, respectively. The variance ratio \( c = \sigma^2_o/\sigma^2_r \) then reduces to \( c = n_r/n_o \), the relative sample size. Without loss of generality we assume that the effect estimate \( \hat{\theta}_o \) from the original study is positive. Furthermore, the equivalence interval \( [-\delta; \delta] \) is assumed to be symmetric around 0 and identical for the original and the replication study.

1.2 Running example

In order to illustrate our methodology, we will use an original study from Goetz et al. [2011] replicated in Sheen et al. [2019, Figure 4A] as part of the RPCB. In the original study, there was no evidence for a difference in primary tumor growth between mice injected with LM-4175 cells with or without a certain intervention (two-sided \( p = 0.34 \)). The replication team also failed to find a significant difference between the groups (two-sided \( p = 0.83 \)). In addition, the combined effect from a fixed effect meta-analysis was not significant (two-sided \( p = 0.47 \)) at both levels mentioned in the replication project, i.e. 0.05 and 0.005. As the original non-significant result was ‘replicated’, replication success was declared with these two criteria in Errington et al. [2021]. The replication report gives the results as correlation coefficients \( r \). We transform them with Fisher’s \( z \)-transformation \( z = \arctanh(r) \) to achieve a normal distribution. The standard error of \( z \) is a function of the effective sample size \( n - 3 \) only: \( \text{se}(z) = 1/\sqrt{n-3} \).

Original and replication effect estimates (on Fisher’s \( z \)-scale) with their 95%-CI are displayed in Figure 1. The standard errors are \( \sigma_o = 0.18 \) and \( \sigma_r = 0.13 \) and so \( c = \sigma^2_o/\sigma^2_r = 1.9 \). Note that the variance ratio \( c \) is equal to the ratio (replication to original) of the effective sample sizes.

This pair of studies will serve as a running example to illustrate our methodology and to highlight why non-significant effects should not be misinterpreted as bearing evidence for no effect. Of course, the design (superiority, non-inferiority, equivalence) of a study should be defined in advance, before the data are collected. The use of this example in this context is therefore for illustrative purposes only.

2 Superiority and non-inferiority designs

The analysis of replication studies with the two-trials rule and the sceptical \( p \)-value approach has already been described for superiority studies [Held 2020, Held et al. 2022]. We start by briefly reviewing these...
2.1 Superiority design

In the replication setting, a one-sided view is generally adopted, i.e. the hypotheses are

\[ H_0 : \theta \leq 0 \text{ vs. } H_1 : \theta > 0. \]  

(3)

The estimate \( \hat{\theta}_o \) of \( \theta \) from the original study can be combined with its standard error to give rise to the original \( z \)-value \( z_o = \hat{\theta}_o / \sigma_o \), and similarly, the replication \( z \)-value is \( z_r = \hat{\theta}_r / \sigma_r \). The \( z \)-values \( z_o \) and \( z_r \) are then transformed into one-sided \( p \)-values \( p_o \) and \( p_r \), respectively, via \( p = 1 - \Phi(z) \), with \( \Phi(\cdot) \) the standard normal cumulative distribution function.

Figure 1: Original study by [Goetz et al. 2011], replication study by [Sheen et al. 2019] and meta-analysis combining the two effects. Shown are the effect estimates on Fisher’s \( z \)-scale with the 95% confidence intervals: \([−0.18; 0.52]\) in the original study, \([−0.23; 0.28]\) in the replication study, and \([−0.13; 0.28]\) for the meta-analysis. The \( p \)-values are two-sided.
2.1.1 The two-trials rule

A replication of superiority is declared successful with the two-trials rule criterion if the two \( p \)-values, \( p_o \) and \( p_r \), are significant at the one-sided level \( \alpha \). This criterion is a standard in drug development [FDA, 1998], where it is common to use a one-sided significance level of \( \alpha = 0.025 \).

For a significant original study \( (p_o \leq \alpha) \), Held et al. [2022] proposed to consider the relative effect size \( d = \hat{\theta}_r / \hat{\theta}_o \) instead of the replication \( p \)-value \( p_r \) for the assessment of the two-trials rule. Using this quantity, the two-trials rule is fulfilled if

\[
d \geq \frac{z_\alpha}{z_o \sqrt{c}}. \tag{4}
\]

The approaches based on the replication \( p \)-value \( p_r \) and on the relative effect size \( d \) are equivalent.

If the relative sample size increases \( (c \uparrow \infty) \) in Equation (4), the lower bound for the relative effect size \( d \) tends to 0. In other terms, conditional on a significant original result, any positive replication effect estimate, regardless how small, can fulfill the two-trials rule if the relative sample size \( c \) is large enough. This is an unwanted property in the replication setting.

2.1.2 The sceptical \( p \)-value approach

Held [2020] proposed an alternative approach for the analysis of replication studies, based on a reverse-Bayes methodology: the sceptical \( p \)-value approach. The methodology consists of two steps: a reverse-Bayes analysis, and a prior-data conflict assessment. A key feature of this approach is that the studies are treated differently and not as exchangeable as in the two-trials rule.

In a nutshell, a significant original result is challenged with a sceptical prior, which is sufficiently concentrated around 0 to make the result no longer convincing (lower bound of the posterior credible interval equal zero) [Matthews, 2001a,b]. The conflict between the sufficiently sceptical prior and the replication study is then quantified by a prior-predictive tail probability [Box, 1980]. Informally, replication success is declared if there is a sufficient conflict between the sceptical prior and the replication study. The precise condition for replication success at level \( \alpha \) is that both \( \text{sign}(z_o) = \text{sign}(z_r) \) and

\[
(\varphi z_o^2 / z_o^2 - 1) (\varphi z_r^2 / z_r^2 - 1) \geq c \tag{5}
\]

must hold, where \( \varphi = (\sqrt{5} + 1) / 2 \) is the golden ratio [Held et al., 2022]. The sceptical \( p \)-value \( p_S \) is the smallest possible value of \( \alpha \) where (5) holds, so replication success at a pre-defined level \( \alpha \) is declared if \( p_S < \alpha \).
Condition (5) can be reformulated in terms of the relative effect size
\[
d \geq \frac{\sqrt{1 + c/(K - 1)}}{\sqrt{cK}} := m
\]
where \(K = \varphi(z_o/z_\alpha)^2 > 1\). For \(c \uparrow \infty\), (6) becomes
\[
d > 1/\sqrt{K(K - 1)}.
\]
The lower bound for \(d\) hence does not tend to 0 as in the two-trials rule, indicating that shrinkage of the replication effect estimate as compared to the original one is penalized with this approach. For \(z_o = z_\alpha\), the right hand-side of (7) becomes 1, so this approach ensures that a borderline significant original study \((p_o = \alpha)\) can lead to replication success only if the replication effect size is larger than the original one.

The operating characteristics of the sceptical \(p\)-value approach have also been investigated, namely the overall type-I error rate (probability to incorrectly declare replication success) and the project power (probability to correctly declare replication success). The overall type I error is controlled at level \(\alpha^2\) for any relative sample size \(c > 0.85\). In addition, the project power is always larger with this approach as compared to the two-trials rule.

### 2.1.3 The meta-analysis criterion

Another criterion for replication success used in many replication projects is a significant combined effect from a fixed effect meta-analysis. The combined effect estimate can be calculated as
\[
\hat{\theta}_{MA} = \left(\frac{\hat{\theta}_o}{\sigma_o^2} + \frac{\hat{\theta}_r}{\sigma_r^2}\right) \left(\frac{1}{\sigma_o^2} + \frac{1}{\sigma_r^2}\right)^{-1}
\]
with standard error
\[
se(\hat{\theta}_{MA}) = \sigma_{MA} = 1/\sqrt{\frac{1}{\sigma_o^2} + \frac{1}{\sigma_r^2}}.
\]
The corresponding \(z\)-value is calculated as \(z_{MA} = \hat{\theta}_{MA}/\sigma_{MA}\) and the one-sided \(p\)-value \(p_{MA} = 1 - \Phi(z_{MA})\). The threshold \(\alpha_{MA}\) for \(p_{MA}\) used in replication projects is usually 0.05 or 0.005 (two-sided). We will use \(\alpha_{MA} = 0.0025\) (one-sided) in this paper. This is a convenient criterion as it combines the two estimates into one with a confidence interval which can be used to assess replication success (by checking whether its lower limit is larger than 0).
It is also possible to reformulate the criterion as a function of the relative effect size \( d \),

\[
d \geq z_{\text{OMA}} \frac{\sqrt{c+1}}{cz_o} - \frac{1}{c},
\]

(10)

with \( z_{\text{OMA}} = \Phi^{-1}(1 - \alpha_{\text{OMA}}) \).

An important limitation of the meta-analysis criterion is that although the original finding might suffer from publication or reporting biases, the two studies are considered exchangeable. This is acknowledged in some replication projects (e.g. in [Camerer et al. 2016], [Errington et al. 2021]). In addition, a significant combined effect might still be detected if one of the studies is not convincing on its own, and even if the effect estimate is in the opposite direction. Furthermore, for \( c \uparrow \infty \), the right term in (10) tends to 0 as in the two-trials rule.

### 2.2 Non-inferiority design

Imagine now that the aim of an original study is not to show superiority of an effect \( \theta \), but non-inferiority, \( i.e. \) the effect \( \theta \) is not smaller than a pre-defined margin \( -\delta \). This type of design is a non-inferiority design and the hypotheses can be formulated as

\[
H_0^- : \theta \leq -\delta \, \text{vs.} \, H_1^- : \theta > -\delta ,
\]

(11)

where \( -\delta \) is the non-inferiority margin. The superscripts ”–” in (11) indicate that a non-inferiority design is used. In fact, the hypotheses (11) are the same as in a one-sided superiority design (see hypotheses (3)), shifted by the margin \( -\delta \). This shift of \( -\delta \) is naturally reflected in the calculation of the corresponding \( z \)-values:

\[
z_o^- = (\hat{\theta}_o + \delta) / \sigma_o \quad z_r^- = (\hat{\theta}_r + \delta) / \sigma_r .
\]

(12)

#### 2.2.1 The two-trials rule

This case is handled the same way as for superiority studies: if \( p_o^- \) and \( p_r^- \) (calculated using (12) with \( p = 1 - \Phi(z) \)) are significant at level \( \alpha \), then the two-trials rule is fulfilled. Let us assume that in our example (see Section 1.2), the original study had a non-inferiority design with a margin \( -\delta = -0.25 \) on Fisher’s \( z \)-scale, which approximately also corresponds to a correlation of 0.25. In this case, the two-trials rule would be fulfilled at level \( \alpha = 0.025 \) as \( p_o^- = 0.01 \) and \( p_r^- = 0.017 \). It is also possible to apply the two-trials rule based on the (somewhat modified) relative effect size instead of the replication \( p \)-value \( p_r \).
The relative effect size \( d = \hat{\theta}_r / \hat{\theta}_o \) is now replaced by \( d^- = (\hat{\theta}_r + \delta) / (\hat{\theta}_o + \delta) \) and the condition on \( d^- \) is

\[
d^- \geq \frac{z_o}{z_o} \sqrt{c}, \tag{13}
\]

the same as in (4) for superiority designs with \( z_o \) replaced by \( z_o^- \) as defined in (12).

2.2.2 The sceptical \( p \)-value approach

Using the example, Figure 2 illustrates the reverse-Bayes procedure for a non-inferiority design.

Figure 2: Example of the assessment of replication success with the sceptical \( p \)-value approach in non-inferiority studies at the one-sided level \( \alpha = 0.025 \) and with a non-inferiority margin \( -\delta = -0.25 \).

The original study of Goetz et al. [2011], significant for the null hypothesis \( H_0 : \theta \leq -\delta = -0.25 \) is challenged with a sceptical prior, sufficiently centered around \( -\delta = -0.25 \) to make the result no longer convincing (lower bound of the credible interval equal to \( -\delta = -0.25 \)). The conflict between the sceptical prior and the replication study is again reflected in a sceptical \( p \)-value, with smaller values indicating a greater conflict.

The sceptical \( p \)-value \( p_S^- \) is obtained by replacing \( z_o \) and \( z_r \) with \( z_o^- \) and \( z_r^- \), respectively, in Equation (5) and turns out to be \( p_S^- = 0.033 > 0.025 \). Replication success of non-inferiority is thus not achieved. We explain why this is so in Section 2.3.
For the equivalent assessment based on the relative effect size, the bound on \( d^- \) is

\[
d^- \geq m^-,
\]

with \( m^- \) defined as \( m \) in (6) with \( z_o \) replaced by \( z_o^- \).

The operating characteristics of this approach are the same as for superiority studies (see Section 2.1.2): the type I error is controlled for \( c > 0.85 \) and there is a gain in project power as compared to the two-trials rule.

### 2.2.3 The meta-analysis criterion

The assessment of replication success of non-inferiority with the meta-analysis criterion is very similar to the superiority setting described in Section 2.1.3. The \( z \)-value

\[
z_{MA}^- = (\hat{\theta}_{MA} + \delta) / \sigma_{MA}
\]

is calculated using the margin \( -\delta \), the combined effect estimate \( \hat{\theta}_{MA} \) and its standard error \( \sigma_{MA} \) derived in (8) and (9). Replication success is declared if \( p_{MA}^- = 1 - \Phi(z_{MA}^-) \leq \alpha_{MA} \). In the example with \( \delta = -0.25 \), \( p_{MA}^- = 0.001 < 0.0025 \), and so replication success is achieved.

Equivalently, the condition on \( d^- \) is

\[
d^- \geq z_{\alpha_{MA}} \sqrt{\frac{1}{c^2}} - \frac{1}{c},
\]

the same as in (10) with \( z_o = z_o^- \).

### 2.3 Comparison of the methods

The application of the two-trials rule and the sceptical \( p \)-value approach to the example illustrates two known properties in superiority studies [Held et al., 2022] which translate to non-inferiority designs. First, the two-trials rule is less stringent than the sceptical \( p \)-value approach when the original \( p \)-value \( p_o^- \) is close to 0.025 while it is more stringent for very convincing original studies. The tipping point \( p_o^\top \) depends on the relative sample size \( c \). For example, for \( c = 1 \) it is \( p_o^\top = 0.006 \) while for \( c = 1.9 \) it is \( p_o^\top = 0.0009 \). This explains why replication success is achieved with the two-trials rule, while it is not with the sceptical \( p \)-value approach in the example (where \( c = 1.9 \) and \( p_o^- = 0.01 > 0.0009 \)). Second, shrinkage of the replication effect estimate as compared to the original one is penalized in the latter approach. It is in contrast not the
case in the other two methods. Another important property of the sceptical \( p \)-value approach is that non-
significant original studies (with \( \alpha = 0.025 < p_o < 1 - \Phi(z_o/\varphi) = 0.062 \)) can still lead to replication success,
while this is obviously not possible with the two-trials rule. The meta-analysis criterion, however, does not
impose significance on each individual study.

### 3 Equivalence design

The correct design when the aim of a study is to ‘show the null-hypothesis’ is an equivalence design. An
equivalence interval \([-\delta; \delta]\) needs to be specified a priori, corresponding to a range of effect sizes which
represents exchangeability of the two treatments considered [Matthews, 2006].

Conceptually, an equivalence study can be seen as the intersection of two one-sided tests, with hy-
potheses (1) and (2).

Furthermore, similarly to hypotheses (1) corresponding to hypotheses (3) shifted by a
constant \(-\delta\), hypotheses (2) correspond to (3), shifted by a constant \(\delta\). We will therefore adapt the methods
described for non-inferiority testing in Section 2.2. Derivations can be found in Web Appendix A.

#### 3.1 The two-trials rule

The two-trials rule applied to an equivalence design amounts to applying the TOST procedure twice – once
for the original and once for the replication study. This results in four one-sided tests with corresponding
\( z \)-values \( z_o^-, z_r^- \) as described in (12) and

\[
z_o^+ = (\hat{\theta}_o - \delta)/\sigma_o \quad \text{and} \quad z_r^+ = (\hat{\theta}_r - \delta)/\sigma_r.
\]

(17)

Let us now imagine that, in the example, the original study from [Goetz et al., 2011] was conducted as an
equivalence study, with an equivalence interval \([-0.25; 0.25]\). In this scenario, the two-trials rule is clearly
not fulfilled as the upper bound of the 95%-CI (0.52) is substantially larger than 0.25, which is also reflected
in the large original \( p \)-value \( p_o^+ = 0.33 \).

Similarly to the bound (13) on \( d^- \), a bound on \( d = (\hat{\theta}_r - \delta)/(\hat{\theta}_o - \delta) \) can be derived as

\[
d^+ \geq \frac{-z_o}{z_o^+ \sqrt{c}}
\]

(18)

In order to have the two-trials rule fulfilled, the two conditions (13) and (18) must hold.

However, the values of \( d^- \) and \( d^+ \) are not easy to interpret and we therefore prefer to work with the
relative effect size \( d = \hat{\theta}_r/\hat{\theta}_o \) instead. In order to do so, we propose a new quantity, the effect estimate relative
to the margin (EERM),

\[ f = \frac{\hat{\theta}_o}{\delta}. \]

In the example, \( f = 0.17/0.25 = 0.68 \), so \( \hat{\theta}_o \) is 68% the size of the margin \( \delta \) or equivalently, is by a factor of \( 1 - f = 32\% \) smaller than the margin \( \delta \).

In the particular case of a null original effect estimate \( \hat{\theta}_o = 0 \), it does not make sense to assess the success of the replication based on the relative effect size \( d \) which would be \( \infty \). In this case, the \( p \)-values \( p_o^- = p_o^+ = 1 - \Phi(\delta/\sigma_o) \) should be used directly. In the following, we hence assume that \( \hat{\theta}_o \) is strictly positive and smaller than \( \delta \) (otherwise it would not make sense to replicate the original study), and so \( f \) lies between 0 and 1.

As we will see, the EERM plays a central role in the analysis of replication studies with an equivalence design. Importantly, it connects the two \( z \)-values \( z_o^- \) and \( z_o^+ \) via the following relationship

\[ z_o^- = \left( f + \frac{1}{f} \right) z_o^+. \tag{19} \]

It is thus sufficient to know one original \( z \)-value (or \( p \)-value) and \( f \) in order to calculate the other. As \( 0 < f < 1 \), we see from Equation (19) that \( |z_o^-| \) is always larger than \( z_o^+ \) and so the \( p \)-value \( p_o^+ \) is always larger than \( p_o^- \). For this reason, we will mostly focus on \( p_o^+ \) in this paper.

Conditions \( d^- \) on \( d^- \) and \( d^+ \) on \( d^+ \) can then be rewritten and transformed to an interval \([d_{\min}; d_{\max}]\) for the relative effect size \( d \), with

\[ d_{\max} = \frac{1}{f} \left( z_{\alpha} \left( 1 - f \right) + 1 \right), \tag{20} \]

and \( d_{\min} = -d_{\max} \). Conditional on a significant original study, the two-trials rule is fulfilled if \( d \) is contained in the interval \([d_{\min}; d_{\max}]\); which is referred to as the \textit{success interval} in the following. The latter only depends on the \( z \)-value \( z_o^+ \) (or \( z_o^- \) via (19)), the relative sample size \( c \) and the EERM \( f \).

Figure 3 (left panel) presents the success interval \([d_{\min}; d_{\max}]\) calculated with (20) as a function of the original \( p \)-value \( p_o^+ \) for \( f = 0.68 \). The interval becomes larger with increasing relative sample size \( c \), and ultimately converges to \([-1/f; 1/f] = [-\delta/\hat{\theta}_o; \delta/\hat{\theta}_o] = [-1.47; 1.47] \) for \( c \to \infty \). In other words, given a significant original study, the two-trials rule can be fulfilled for any \( |\hat{\theta}_c| < \delta \) if the relative sample size \( c \) is sufficiently large.
Figure 3: Comparison of the success intervals $[d_{\min}; d_{\max}]$ based on the two-trials rule (2TR, Equation (20)), the sceptical $p$-value approach (pS, Equation (22)), and the meta-analysis criterion (MA, Equation (24)) at level $\alpha = 2.5\%$ for 2TR and pS and $\alpha_{MA} = 0.0025$ for MA. The EERM is $f = 0.68$ corresponding to the examples. The grey and green dots indicate, respectively, the relative effect size $d$ in the modified and running example. The blue lines on the middle plot illustrate that the upper bound on $d$ is 1 for $c = \infty$ if $p_0^+ = \alpha = 0.025$. $p_0^-$ on the top axis is a function of $d$ through Eq (19).

3.2 The sceptical $p$-value approach

In this setting, an original finding (with an equivalence design) is challenged with two sceptical priors, which are sufficiently concentrated around the margin $\delta$ (respectively $-\delta$) to make the original result no longer convincing: the upper (respectively lower) limit of the posterior credible interval is exactly at the equivalence margin $\delta$ (respectively $-\delta$). The two sceptical priors are in general not identical and their width depends on the original $p$-values at each margin, $p_0^+$ and $p_0^-$, respectively, with a larger $p$-value leading to a larger variance of the sufficiently sceptical prior. In order to reflect the conflict between the replication study and each sceptical prior, two sceptical $p$-values $p_S^+$ and $p_S^-$ are calculated. The sceptical $p$-value $p_S^-$ was derived in Section 2.2.2, and $p_S^+$ can be computed in the same way using (5) with $z_o = z_o^+$ and $z_r = z_r^+$. Both $p_S^-$ and $p_S^+$ need to be smaller than $\alpha$ in order to achieve replication success.

This procedure resembles the usual TOST procedure: two one-sided tests are conducted; and both need to be convincing in order to declare a successful replication. The difference is that the sceptical TOST procedure notifies about the success of the replication attempt whereas the usual TOST procedure applied to original or replication study informs about the result of each study separately. In the example, the two sceptical $p$-values are $p_S^- = 0.033$ and $p_S^+ = 0.30$, so replication success of equivalence cannot be declared.
The lower bound on $d^+$ to achieve replication success can also be derived and is

$$d^+ \geq m^+, \quad (21)$$

where $m^+$ is defined as $m$ in (6) with $z_o^+$ replacing $z_o$. It is again more convenient to reformulate Equations (14) and (21) in terms of a success interval $[d_{\min}; d_{\max}]$ for the relative effect size $d$:

$$\left[ \frac{m^-(f + 1) - 1}{f}; \frac{m^+(f - 1) + 1}{f} \right]. \quad (22)$$

As before, in the singular case $\hat{\theta}_o = 0$ (where $f = 0$) the success interval (22) is not suitable for the assessment of replication success and the sceptical $p$-values $p^-_S$ and $p^+_S$ should be used instead.

Figure 3 (center panel) displays the success interval as a function of the original $p$-values $p^+_o$ for $f = 0.68$. This interval becomes larger with increasing relative sample size $c$; however, it does not converge to $\pm 1/f = \pm 1.47$ for very large $c$ as it is the case with the two-trials rule. Figure 3 also highlights the asymmetry of the success interval and the possibility for non-significant original studies ($p^+_o > \alpha$) to reach replication success. These properties will be discussed in Section 3.5. Furthermore, the sceptical $p$-value approach prevents a borderline significant study ($p^+_o = \alpha$) from achieving replication success if the relative effect size $d$ is larger than 1 (the blue point in the center panel of Figure 3). Shrinkage of the replication effect estimate as compared to the original one is therefore encouraged in equivalence studies, while it is penalized in superiority studies.

It is important to note that Figure 3 is specific to one particular EERM ($f = 0.68$) and will look different for another value of $f$. This will be discussed and illustrated in a later section, as well as in Web Figure 1.

### 3.3 The meta-analysis criterion

The meta-analysis criterion applied to equivalence studies also uses the TOST procedure: the combined effect estimate $\hat{\theta}_{MA}$ needs to be significant at level $\alpha_{MA}$ for both null hypotheses in (1) and (2). The $p$-values $p^-_{MA}$ and $p^+_{MA}$ are calculated from $z^-_{MA}$ in (15) and

$$z^+_{MA} = (\hat{\theta}_{MA} - \delta)/\sigma_{MA}, \quad (23)$$

respectively. That is the same as checking whether both limits of the meta-analytic CI are contained in the equivalence interval $[-\delta; \delta]$. Formulation in terms of a success interval for the relative effect size $d$ is also
possible and the success interval $[d_{\text{min}}; d_{\text{max}}]$ is

$$\left[ \frac{z_{\text{MA}} \sqrt{c f} f}{c f z_o^2} - \frac{c + 1}{c f} - \frac{1}{c f} \frac{-z_{\text{MA}} \sqrt{c + 1}(f - 1)}{c f z_o^2} + \frac{c + 1}{c f} - \frac{1}{c f} \right].$$

(24)

Figure 3 (right panel) shows the success interval of the meta-analysis criterion at level $\alpha_{\text{MA}} = 0.0025$ (one-sided) and for $f = 0.68$. The meta-analysis criterion is not fulfilled in the example.

### 3.4 Application to modified running example

Replication success of equivalence cannot be declared with either method in the example presented in Section 1.2 with the margin $\delta = 0.25$. This is mainly due to the original study having a wide confidence interval. Only with an implausibly large margin (larger than $\delta = 0.52$ which corresponds to 0.48 on the correlation scale) could equivalence be declared. This illustrates why a non-significant study should never be interpreted as showing evidence for no effect – even though the effect estimate in the study from Goetz et al. [2011] is small and the corresponding 95% confidence interval crosses 0, the uncertainty is too large to declare equivalence with a reasonable equivalence margin. The results of this study should therefore be labeled as inconclusive instead.

In order to illustrate several aspects of the methods, we will now use a modified version of the example, where the effect from the original study $\hat{\theta}_o = 0.17$ is the same, but the standard error is divided by a factor of 4, i.e. $\text{se}(\hat{\theta}_o) = 0.045$. The effect estimate from the replication study $\hat{\theta}_r = -0.03$ has the same magnitude as in the example, but is negative, and its standard error is also divided by 4 ($\sigma_r = 0.033$). As a result, the original and replication 95%-CI are now $[0.08; 0.26]$ and $[-0.09; 0.04]$, respectively, the relative effect size is $d = -0.16$ and the relative sample size $c = 1.9$ stays the same. We again assume an equivalence interval of $[-0.25, 0.25]$. The modified example is displayed in Figure 4.

Replication success in this modified example can easily be assessed using Figure 3. The two-trials rule is not fulfilled as $p_{\text{o}}^+ = 0.037 > 0.025$. In contrast, replication success is achieved with the sceptical $p$-value approach and the meta-analysis criterion.

### 3.5 Properties

Some properties and differences between the different approaches have been mentioned in their respective sections already. In this section, the differences between the methods are discussed in more detail.
Figure 4: Original and replication studies of the modified example. Shown are the effect estimates on Fisher’s z-scale with the 95% confidence intervals: [0.08; 0.26] in the original study and [−0.09; 0.04] in the replication study. The horizontal blue lines indicate the equivalence margin ±δ = ±0.25. The p-values have been calculated using (12) and (17).

3.5.1 Stringency of the methods

This paragraph will focus on comparing the stringency of the two-trials rule and the sceptical p-value approach, i.e. how demanding it is to fulfill each criterion in terms of the relative effect size $d$. In the superiority (and non-inferiority) setting, it is sufficient to just compare the bounds on the relative effect size $d$, i.e. conditions (4) vs (6), with smaller values indicating a more relaxed condition. It is not as straightforward in equivalence studies, as there are two bounds. We propose to use the success interval width $w = d_{\text{max}} - d_{\text{min}}$ as an indicator of stringency. To compare the width for the two-trials rule and for the sceptical p-value approach we consider the relative interval width $\tilde{w} = w_{ps} / w_{2TR}$.

Figure 5 displays the relative interval width $\tilde{w}$ as a function of $p^+_o$ for different relative sample sizes $c = 1, 1.9$ (as in the examples) and $10$ and different values of the EERM: $f = 0.1, f = 0.68$ (as in the examples), and $f = 0.9$. In all three cases, the sceptical p-value approach tends to disfavor borderline significant original studies (where $\tilde{w} < 1$) and promote more compelling original studies (where $\tilde{w} > 1$) as compared to the two-trials rule. However, if the relative sample size is large, the two-trials rule is less stringent than the sceptical p-value approach for almost all values of $p^+_o$. For example, for $c = 10$ and $f = 0.68$, the sceptical p-value approach is slightly less rigorous than the two-trials rule only if $p^+_o < 0.000031$. This is one of the major differences between the two approaches and a consequence of the fact that increasing the sample size
Figure 5: Relative interval width \( \tilde{w} (w_{pS}/w_{2TR}) \) as a function of the original p-value \( p_0^+ \) for fixed EERM \( f \).

does not push the bounds \( d_{\min} \) and \( d_{\max} \), towards \( \pm 1/f \) as it is the case for the two-trials rule. This can also be illustrated with the modified example: an infinitely large replication study would still need to produce a relative effect size in the interval \([-1.41; 0.78]\) in order to be successful with the sceptical p-value approach.

The influence of the EERM can also be seen in Figure 5; as \( f \uparrow 1 \), the relative interval width \( \tilde{w} \) tends to 1, i.e. the two approaches are similar if \( \hat{\theta}_o \) is close to the margin \( \delta \).

The meta-analysis criterion has been excluded from this comparison as it presents a fundamental drawback: it is possible for relative effect sizes smaller than \(-1/f = -\delta/\hat{\theta}_o\) to lead to replication success. For example, as can be observed in Figure 3 (right panel), an original study with \( p_0^+ = 0.1 \) and a relative effect size of \(-2.5\) - so a replication effect size considerably smaller than \(-\delta\) - will fulfill the meta-analysis criterion if \( c = 1 \). However, the evidence for equivalence is small in both studies, and this highlights why meta-analysis is not suited in the replication setting.

In the comparison, only original studies with \( p_0^+ \leq \alpha = 0.025 \) are considered as it is a necessary condition for the two-trials rule. In contrast, the other two approaches tolerate non-significant original studies as demonstrated in the next paragraph.

### 3.5.2 Non-significant original study

The strong cut-off at \( \alpha \) for the p-value is not as pronounced in the sceptical p-value approach. Non-significant original studies can still lead to a replication success with this criterion, as can be observed with the modified example. For \( \alpha = 0.025 \), the largest value of \( p_0^+ \) where this is possible varies between 0.025 and 0.062 depending on the EERM \( f \). Smaller \( f \) lead to more stringent bounds, see Web Figure 2 for
more detail. This makes sense, as for the same $p^+_o$, an original study with an effect estimate close to the margin (EERM $\approx 1$) will have a smaller $p^-_o$, than an original study with an effect estimate close to 0 (EERM $\approx 0$). With $f = 0.68$ (as in the examples), the upper bound on $p^+_o$ is 0.059, so it is possible for any original study with $p^+_o < 0.059$ to achieve replication success with the sceptical $p$-value approach. The latter also ensures that replication success is not declared with non-significant original studies if $\hat{\theta}_r > \hat{\theta}_o$.

In contrast, significance of each individual study is absolutely not taken into account in the meta-analysis criterion. It can be observed in Figure 3 (right panel) that an increase in sample size allows original studies with a large $p$-value to lead to replication success. In the extreme case where $c = \infty$, any study with $p^+_o < 0.5$ is able to fulfill the meta-analysis criterion for any $|d| < 1/f$, i.e. $|\hat{\theta}_r| < \delta$. For example, if the sample size in the example was $c = 10$ instead of $c = 1.9$, replication success would have been declared, even with an original $p$-value as large as $p^+_o = 0.33$.

### 3.5.3 Asymmetry

The success interval of the two-trials rule in (20) is symmetric around 0. In contrast, the success intervals of the sceptical $p$-value approach in (22) and of the meta-analysis criterion in (24) are generally asymmetric and more stringent in the direction of the original effect estimate $\hat{\theta}_o$, i.e. they prefer estimates in the other direction. That can be observed in Figure 3 (center and right panels): as the original effect estimate is positive, the criterion for replication success is less stringent for negative replication effect estimates. In the modified example, the success interval is $[-1.17; 0.72]$ and $[-2.12; 1.05]$ with the sceptical $p$-value approach and the meta-analysis criterion, respectively. With the former approach, the asymmetry tends to vanish with smaller EERM. This is coherent: as $f$ tends to 0, $p^-_o$ tends to $p^+_o$, and the evidence tends to be the same in both one-sided assessments of replication success.

### 4 Discussion

The adaptation of the methodology used in superiority studies to non-inferiority settings can be done by shifting the point null hypothesis to a (negative) non-null value, shift which is also reflected in the calculation of the $p$-values. The same methods as in superiority settings can then be applied. In contrast, equivalence studies are more involved as they consist of the intersection of two one-sided tests. We propose to adapt the TOST procedure and reformulate the conditions for replication success in terms of success intervals for the relative effect size $d$.

For all types of designs, the sceptical $p$-value approach is less stringent than the two-trials rule for very convincing original studies, and vice versa. In equivalence designs, it allows non-significant original stud-
ies to reach replication success, provided that the replication effect estimate is not larger than the original one. The strong cut-off at $\alpha$ for the $p$-value is thus not present with this approach, and the available evidence in both one-sided tests is acknowledged. In contrast to the two-trials rule, the sceptical $p$-value approach takes into consideration the direction of the original effect and is more rigorous with replication effect estimates in the same direction, especially if the evidence from the original study was weak.

There are significant deficiencies in the meta-analysis criterion, making this analysis strategy unsuitable in the context of replication studies. First, in addition to allowing any absolute replication effect estimate smaller than the margin $\delta$ to lead to replication success as long as $c$ is large enough (as the two-trials rule), it also accepts replication effect estimates smaller than $-\delta$ and original studies with $p$-values inconceivably large.

Some limitations need to be noted. First, our methodology relies on normality of the effect estimates, which might seem restrictive. However many framework fall into this category after a suitable transformation. Moreover, the type I error rate and the project power have not been derived for equivalence studies. This will be discussed in a subsequent paper. Future work will also focus on the sample size calculation in replication studies with an equivalence design, similarly to what is presented in Micheloud and Held [2022] for superiority studies. Furthermore, we will adapt this framework to sequential designs, i.e. an interim analysis takes place during the course of the replication study.
