Atmospheric Turbulence Removal with Complex-Valued Convolutional Neural Network

Nantheera Anantrasirichai*
University of Bristol

Abstract

Atmospheric turbulence distorts visual imagery and is always problematic for information interpretation by both human and machine. Most well-developed approaches to remove atmospheric turbulence distortion are model-based. However, these methods require high computation and large memory preventing their feasibility of real-time operation. Deep learning-based approaches have hence gained more attention but currently work efficiently only on static scenes. This paper presents a novel learning-based framework offering short temporal spanning to support dynamic scenes. We exploit complex-valued convolutions as phase information, altered by atmospheric turbulence, is captured better than using ordinary real-valued convolutions. Two concatenated modules are proposed. The first module aims to remove geometric distortions and, if enough memory, the second module is applied to refine micro details of the videos. Experimental results show that our proposed framework efficiently mitigate the atmospheric turbulence distortion and significantly outperforms the existing methods.

1 Introduction

Light propagating through atmospheric turbulence, caused by heat sources at different temperatures, appears as a combination of blur, ripple and intensity fluctuations in the video sequences. This phenomenon obviously deteriorates the visual quality and the performance of computer vision techniques, including face detection, object tracking, 3D rendering, etc. Mitigating the atmospheric turbulence distortion has been attempted both online and offline. The online system is integrated in the optical device to operate in real time but visual quality is limited, whilst the offline approach aims for better restoration results, but it could be slow even using high performance computing machines.

Mathematically, the model of atmospheric turbulence effects is generally expressed as \( y = Dx + n \), where \( x \) and \( y \) are the ideal and observed images respectively, \( D \) represents unknown geometric distortion and blurs from the system, and \( n \) represents noise. Despite being simple, this problem is irreversible thereby leaving imperfect solution in practice. Traditional methods have solved this problem by modelling it as a point spread function (PSF) and then employing blind deconvolution with an iterative process to estimate \( x \) \[^1\]. Alternatively, image fusion techniques, where only good information among frames are selected to reconstruct a new clearer frame, achieve desirable restoration performances \[^2\]. However, there are two major problems

*This work was funded by the UKRI MyWorld Strength in Places Programme (SIPF00006/1).
Atmospheric Turbulence Removal with Complex-Valued Convolutional Neural Network

with these model-based methods: i) high computational complexity, meaning that a real-time implementation is almost impossible, ii) artefacts from moving objects due to imperfect alignment created when combining multiple images [3].

Deep learning has emerged as a powerful tool to find patterns, analyse information, and to predict future events. These capabilities make the learning-based techniques widely used in image and video applications [4]. For the atmospheric turbulence removal, deep learning is still in the early stage and all proposed methods are based on convolutional neural networks (CNNs). The first deep learning-based method, proposed by Gao et al., [5], follows the assumption that the spatial displacement between frames due to atmospheric turbulence has Gaussian distribution. The state-of-the-art Gaussian denoiser, DnCNN [6], architecture is hence used. Later, the method proposed in [7] employed UNet architecture, which is originally introduced for medical image segmentation [8]. They adjusted the input channels of the UNet to accept a 50-frame concatenated volume and the output was a single restored frame. As this method requires a long length of inputs, it is infeasible to restore the distorted videos with moving objects. Vinta et al. [9] have investigated the performance of mitigating atmospheric turbulence effect with various state-of-the-art architectures, originally proposed for denoising, deblurring, and super-resolution. The results from their report are very promising. However, they studied only on the synthetic static scenes.

Some proposed methods, that involve supervised learning, imitate a traditional workflow of the model-based techniques. Firstly, the reference frame is constructed. A series of frames are subsequently registered to this reference frame, and then the registered frames are averaged. Finally, a deep learning-based deblurring technique, e.g. DnCNN [10] and pyramid fusion network [11], is applied to sharpen the averaged frame. Obviously they are not end-to-end deep learning-based frameworks and the computational speed is not reduced. More recent methods proposed end-to-end deep learning architectures. A WGAN (Wasserstein generative adversarial network) is employed in [12], where the multiple lucky frames are fed into the UNet generator. This however appears only to work well for static scenes. A framework in [13] comprises two CNNs: i) phase aberration correction and ii) Zernike coefficients reconstruction. However, only one small image result is reported, so its performance cannot be commented. As ground truth is unavailable for the atmospheric turbulence problem, a self-supervised technique has been proposed in [14], where geometric distortion is removed using a grid-based rendering network. The method estimates spatial displacements between the distorted frames. The clean frame is consequently the output when the zero-displacement map is fed. This method however requires deblurring as post-processing and also needs ten input frames, so it may not work properly if moving objects present.

In this paper, we aim to exploit deep learning mechanism to mitigate atmospheric turbulence distortion in the video sequences. We restrict our framework to require a small number of inputs so that i) it can operate in real time, and ii) it will not create artefacts due to unachievable alignment through multiple convolutional layers, particularly when fast moving objects present. Restoring the video is done in the temporal sliding window. Our framework comprises two modules, aiming to remove geometric distortion and to enhance visual appearance, called a distortion mitigating module and a refinement module, respectively. Our networks operate with complex numbers, representing with richer properties of phase than the real numbers. This is directly inspired by our previous work [2,3,15], where the process is done in the complex wavelet domain. Additionally, deep complex networks [16] have proved superior performance in image recognition over the real-valued only networks. We describe our version of a complex-valued
CNN in Section 2 and our network architecture in Section 3.

As stated above, the restoration of atmospheric turbulence distortion is a ill-pose problem. Ground truth is generally not available. We then intensively test our framework that is trained with a combination of the synthetic and the real datasets, where pseudo ground truth is generated for the real dataset. In Section 4, the training and test datasets are described, followed by the experimental results and discussion. Finally the conclusion of this work is present in Section 5.

2 Mitigating turbulent distortion with complex-valued convolutional neural networks

2.1 Why complex values?

Turbulent medium causes phase fluctuations [17]. This exhibits in the image as phase shift in Fourier domain and in wavelet domain, and the amount depends approximately linearly on displacement [18, 19]. Following quasi-periodic property, the ripple effect of the atmospheric turbulence causes micro displacement between frames with random amount and direction [20]. The phase of each pixel is consequently altered randomly, whilst the magnitude of high frequency may be decreased due to mixing signals, leading to blur on the image. Many simulated methods also model atmospheric turbulence in phase domain. For example, authors in [21] describe atmospheric turbulence effects with wavefront sensing principles, and employ phase diversity to estimate severity level. Chimitt et. at. [22] model phase distortion in a function of frequency, focal length, aperture diameter and a random vector. They show that the phase distortion introduces a random tilt to the PSF. With above reasons, we therefore employ complex-valued convolution to extract phase fluctuations and atmospheric turbulence distortion is removed in both real and imaginary components.

2.2 Complex-valued convolutional layer (CConv)

Similar to previous work [16, 23], implementing complex-valued convolution is straightforward. We define that a feature value $I$ in the feature map has a complex value as $I = I_{\Re} + iI_{\Im}$, where $i = \sqrt{-1}$ is the imaginary unit, $I_{\Re} = \Re\{I\}$ and $I_{\Im} = \Im\{I\}$ are the real and the imaginary components, respectively. With the distributive property, the convolution ($*$) of $I$ and a complex-valued kernel $H = H_{\Re} + iH_{\Im}$ is then expressed as

$$I * H = (H_{\Re} + iH_{\Im}) * (I_{\Re} + iI_{\Im}) = (H_{\Re} * I_{\Re} - H_{\Im} * I_{\Im}) + i(H_{\Re} * I_{\Re} + H_{\Im} * I_{\Im}). \tag{1}$$

Eq. 1 can be straightforwardly implemented with four separate convolutions of the exiting tools, e.g. `torch.nn.Conv2d` in PyTorch. We do not use a pooling layer, but down-sampling feature maps is done through the transposed convolution with a stride of 2 (CConvTran).

2.3 Complex-valued activation function

For an activation function, we select the rectified linear unit function, ReLU, because of its simplicity. The experiment in [23] shows that applying the ReLU function to the real and
imaginary parts separately achieves better image reconstruction than applying to the magnitudes alone. Therefore, our complex ReLU function, CReLU, is defined as $\text{CReLU}(I) = \text{ReLU}(I_\mathbb{R}) + i\text{ReLU}(I_\mathbb{I})$.

For more stable training, we employ the leaky ReLU activation function. This prevents the ‘dying ReLU’ problem, where zero gradients happen when spikes of high frequencies due to spatially turbulent variation amongst frames occur in several training batches consecutively. The leaky ReLU allows a small gradient when the unit is not active (negative inputs) so that the backpropogation will always update the weights. We set the gain $\alpha$ of the leaky ReLU for the negative values to 0.2, and our complex-valued leaky ReLU (CLReLU) is defined as

$$\text{CLReLU}(I) = LReLU(I_\mathbb{R}) + iLReLU(I_\mathbb{I}).$$

(2)

2.4 Batch normalisation

Batch normalisation generally improves stability of the training process. We have tried to normalise the feature maps using the method proposed in [16] and using a batch norm function for real values [24]. With both techniques, the colours of results become flatten. So, we have decided not to create new normalisation for complex-valued tensors, nor apply any normalisation process within our complex-valued neural network as used in the applications of classification and Gaussian denoising. Instead, we scale and shift the input images to $[-1, 1]$ and utilise the element-wise hyperbolic tangent function ($\text{Tanh}$) to cap the output to $[-1, 1]$.

3 Proposed architecture

The proposed end-to-end framework comprises two modules as shown in Fig. 1. The input is a group of distorted frames, $I_{\text{Atmos}} = \{I_{t+n}\}_{n \in [-N_b,N_f]}$, where $t$ is the current timestamp, $N_f$ and $N_b$ are the numbers of forward and backward frames, respectively. The output is the restored version of the current frame, $I_{\text{Final}}$. We call the first one as a distortion mitigating module, where the geometric distortion due to atmospheric turbulence is removed, giving the output $I_{\text{DM}}$ (described in Section 3.1). The second module is for detail refinement, called a refinement module (described in Section 3.2). This second module is to ensure the sub-details in feature and spatial spaces are as close as those of the ground truth.

Figure 1: Diagram of the proposed framework with loss functions for training. The input $I_{\text{Atmos}}$ is a group of distorted frames, $I_{\text{gt}}$ is a clean current frame.
Atmospheric Turbulence Removal with Complex-Valued Convolutional Neural Network

Figure 2: Distortion mitigating module combining of the encoder to extract distorted features and the decoder to reconstruct distorted-free frame. The distorted-suppressed frames $I_E^s$ in several resolutions at the encoder are bridged with the decoder by concatenation. At the decoder the edge features are added up to create sharper frame $I_D^s$. The number shown at each sub-module is associated with the name listed in Table 1.

3.1 Distortion mitigating module

The diagram of the proposed network is illustrated in Fig. 2 and the network configuration are listed in Table 1. The number of input frames is $N_t = N_b + N_f + 1$. The number of output frames is also $N_t$ if the refinement module is enabled; otherwise the number of the output is one, which is the current frame. Our distortion mitigating module is an encoder-decoder architecture with the connection between distorted-free features restored at the encoder and the decoder (appearing as $I_E^s$ in Fig. 2, where $s$ is the resolution level with the maximum level of $S$). The encoder part estimates geometric distortion at different resolution level. Each feature extraction module (green block) comprises nine $3 \times 3$ CConvs, and each CConv is followed with a CLReLU. We reduce and increase the size of the feature maps with a $4 \times 4$ convolution and a $4 \times 4$ CConvTran, respectively, with a stride of 2. The output of each feature extraction module is 64 feature maps, $\{I^c\}_{c \in [0,63]}$.

We include the residual extraction sub-modules (pink block) to convert the distortion represented in complex-valued feature space to the image space. The output of the residual extraction module is subtracted from the distorted inputs. The complex-valued output is converted back to real-valued image, producing distort-free images with real values $I_E^s = |I^c|^s$.

At the decoder, the features of the $I_E^s$ are extracted and concatenated to the features decoded from the inner-most module (gray block). Then the residual extraction sub-modules are exploited again to extract the high frequencies, such as edges and structures, to add in $I_D^s$ to enhance sharpness of the final image $I_{DM}$. This is done in the pyramid manner which has proved its success in image restoration not only when using the CNNs [25], but also wavelet-based reconstruction [15].
Atmospheric Turbulence Removal with Complex-Valued Convolutional Neural Network

Table 1: Configuration of the distortion mitigating module. Dimension of the feature map is $\text{high} \times \text{width} \times \text{channels}$ in complex-valued format (one channel has real and imaginary components). $N_t$ is the number of frames. Colour videos are used here. We simply concatenate R, G and B, resulting total $3N_f$ channels. If not indicate, the convolution is applied with a stride (st) of 1.

Conv: Convolutional layer, CConv: Complex-valued convolutional layer, CConvTran: Complex-valued transposed convolutional layer, st: stride, LReLU: Leaky ReLU, CLReLU: Complex-valued Leaky ReLU

3.2 Refinement module

The first module generally reduces geometric distortion significantly. However, when facing strong atmospheric turbulence, the remaining effect caused from spatial variation of unknown PSF requires deblurring process. We simply adapt UNet architecture [8] with complex-valued convolution to deal with this. We set the depth of our complex-valued UNet to 5, which is reasonable for the input size of $256 \times 256$ pixels. The real-to-complex sub-module, similar to that used in the distortion mitigating module, is attached before the complex-valued UNet. At the end, the complex-to-real sub-module is added to give the final output $I_{\text{Final}}$.

3.3 Loss functions

Our training loss, $L_{\text{Train}}$ is computed using a combination of three loss functions, Charbonnier loss, Laplacian pyramid loss [26] and $\ell_2$, as shown in Eq. 3. In the distortion mitigating module, the pixel-wise loss due to atmospheric turbulence effect might create some outliers. The Charbonnier loss is therefore used because it combines the benefits of $\ell_1$ and $\ell_2$ appearing to handle outliers better [25]. It is defined as $L_{\text{Char}}(x) = \sqrt{x^2 + \epsilon^2}$, $\epsilon = 1 \times 10^{-3}$. This loss captures the content similarly between the reconstructed images and the ground truth in different resolution level, $s \in S$. Here we employ 4 resolution levels, i.e. $S \in [0, \ldots, 3]$, $I_D = I_{\text{DM}}$ (see Fig. 2).

Laplacian pyramid loss $L_{\text{Lap}}$ is applied at the final output of the refinement module. This
is to ensure that image structures presenting at a different scales are similar to those of the ground truth. Following \[26\], $L_{\text{Lap}} = \sum_j 2^{2j} |\Lambda^j(I_{\text{Final}}) - \Lambda^j(I_{\text{gt}})|_1$, where $\Lambda^j(x)$ is the $j$-th level of the Laplacian pyramid representation of $x$. The output of the refinement module will no longer suffer from the atmospheric turbulence distortion, leading to significant lower outliers compared to the output of the first module. Therefore we include a mean-square-error loss, $L_{\text{Refine}}$, instead of the Charbonnier loss, to maximise content and colour similarities to the ground truth.

$$L_{\text{Train}} = \sum_s L^s_{\text{Char}} + L_{\text{Lap}} + L^\text{Refine}_{\ell_2}$$

4 Experiments and discussion

We trained and tested our proposed framework with both synthetic and real datasets, and then compared the performance with some related work. Most existing methods are however developed for static scenes \[10\]-\[13\], and some of them are not truly end-to-end deep learning frameworks \[10\],\[11\]. Also, their source codes are not available at the time of writing. Therefore, we compared the performance of our method with state of the arts of the image and video restoration: i) UNet \[8\], the backbone architecture of many image denoisers and restorers \[27\], ii) EDVR \[28\], the winning solution in NTIRE19 Challenges on video restoration, and iii) FFDNet \[29\] offering the best denoising performance reported in many surveys \[4\],\[30\].

For fair comparison, all methods were modified to accept multiple frames, and were retrained with our datasets. If not indicated, the input $N_t$ was 5 consecutive frames ($N_b$=$N_f$=2) and the model was trained using temporal sliding window procedure for 200 epochs. Adam optimizer was employed with an initial learning rate of 0.0001. All experiments were carried out using the computational facilities of the Advanced Computing Research Centre, University of Bristol (http://www.bristol.ac.uk/acrc/).

4.1 Datasets

The main challenge of the atmospheric turbulence restoration is lack of ground truth in the real scenario. Some existing datasets provide the clean ground truth, but they are all in the static scenes \[15\],\[31\]. The Open Turbulent Image Set (OTIS) \[32\] is the only dataset captured in the dynamic scenes. However, it aims for object tracking, so the ground truth is the boundary box around the moving car toy, rather than the clean sequence. We therefore generated the synthetic datasets, used the pseudo ground truth for the real datasets, and then trained the models using a combination of them.

Our real dataset contains 14 paired videos, available at https://bit.ly/CLEAR_datasets, ranging from 100 frames to 4,000 frames with different resolutions. The longer videos include panning and zooming. The pseudo ground truth of the real datasets was generated off-line using CLEAR method \[3\]. For the synthetic data, we created seven 480×800 atmospheric turbulence sequences using nine predefined PSFs of atmospheric turbulence provided in \[31\]. The process was done in frame-by-frame basis. The spatially variant blur was created by applying the randomly selected PSF to the different parts of the image, and for each image the PSFs were resized randomly so that the strength of ripple effects and degree of blur vary between frames.

Finally, a Gaussian noise with zero mean and random variance was added. These synthetic datasets are available at [https://bit.ly/Synthetic datasets](https://bit.ly/Synthetic datasets).

### 4.2 Synthetic examples

The experiments on the synthetic examples aim to perform objective quality assessment as ground truth is known. We exploit PSNR and SSIM applied to each frame in the sequence and the results shown are the average of all test frames. If the videos are in colour, we compute PSNR and SSIM each colour channel separately and the results are averaged. The results shown in Table 2 reveal that the proposed method achieves the best performance, which improves the visual quality by 20% and 7% from the raw distorted sequences in term of PSNR and SSIM, respectively.

### 4.3 Real atmospheric turbulence sequences

The objective quality assessment is done by comparing with the pseudo ground truth and the results are shown in Table 2. This may not well reflect the true performance comparison, but it can be seen as how well the methods can remove the temporal variation, since CLEAR method achieves desirable mitigation of the atmospheric turbulence effect (see the y-t and x-t planes of CLEAR in Fig. 3 and Fig. 4).

The subjective results are shown in Fig. 3 and 4 (zoom in for better visualisation and comparison). The restored frames reveal how smooth the edges are recovered and how much detail is restored. These CNN-based methods produce smoother straight lines than the pseudo ground truth generated from CLEAR, but the edges are not as sharp. We also show the cross sections of the video sequences in x-t or y-t plane to demonstrate how much ripple effect is suppressed. The proposed method clearly produce better visual quality than other methods. EDVR performs well only when the atmospheric turbulence distortion is subtle, like the ‘car’ sequence in Fig. 4. FFDNet cannot reduce the ripple effect and some signals are clipped.

### 4.4 Ablation study

#### 4.4.1 Real-valued vs complex-valued convolution

We studied the effect of using complex values by comparing the performance of the traditional UNet with the complex-valued UNet. Some results of the synthetic and real datasets are shown in Fig. 5. As expected, the complex-valued UNet can remove the ripple effects more, and
Atmospheric Turbulence Removal with Complex-Valued Convolutional Neural Network

Figure 3: Subjective comparison of ‘Van’ sequences. Top-Middle: x-y frame at t=32. Bottom: y-t plane at x = 50. The CLEAR results are used as pseudo ground truth.

Figure 4: Subjective comparison of ‘Car’ sequences. Top-Middle: x-y frame at t=132. Bottom: x-t plane at y = 140. The CLEAR results are used as pseudo ground truth.
produces better temporal consistency than the real-valued UNet. This can be seen at the area near the letter ‘N’ of the ‘Train’ sequence, where motion artefact clearly presents. Additionally, the restored results of the complex-valued UNet appear to be sharper than those of the real-valued one.

The complex-valued convolutions require more memory and training time than the conventional convolutions. On the 640×360 sequences, the complex-valued UNet generates the restored results approximately 50 frame/sec, whilst the real-valued UNet takes about 60 frame/sec. Another drawback of the complex-valued convolution we found is that sometimes the model loses one colour channel which consequently requires more training iterations to recover it, or restarting the training process.

4.4.2 With vs without refinement module

The aim of the refinement module is to remove the remaining distortion after the distortion mitigating module. Testing with the synthetic datasets, the quality of the restored results is improved the PSNR values up to 1.5 dB, and the SSIM values up to 0.085. The results in Fig. 6 demonstrate the case that the distortion mitigating module alone leaves some blur and motion artefacts, whilst the refinement module further remove these distortions, leading to sharper results. The refinement module however adds computational time approximately 35%.

4.4.3 Number of input frames

It is well studied with the model-based methods that removing the atmospheric turbulence effects with a single image is almost impossible, and the more the number of input frames, the better the restoration. This is however valid only the static scenes or the static background areas. When the moving objects appear in the scene, the imperfect alignment could cause motion artefacts. Our proposed framework employs neither the optical flow estimation nor wrapping module; therefore, the number of input frames may be limited when fast moving objects present.
Atmospheric Turbulence Removal with Complex-Valued Convolutional Neural Network

Figure 7: Average quality of restoration using different number of input frames. 0 indicates the visual quality of the distorted frames

Fig. 7 show the restored qualities of different numbers of input frames ($N_t$, where $N_b=N_f$). The average PSNRs and SSIMs indicate that five frames are the optimal number for our datasets.

5 Conclusion

This paper introduces a deep learning-based approach to mitigate atmospheric turbulence distortion on the dynamic scenes. Our proposed framework is based on complex-valued convolutions, where amplitudes and phases of local features are fully exploited to remove geometric distortion and to enhance edge and structure information. The framework comprises two modules: distortion mitigating and refinement modules. The models are trained with a combination of synthetic and real datasets. Experiments show that our method performs well even in strong atmospheric turbulence scenes.
