Her research interests include design of complex experiments, Bayesian inference, spatial statistics, and topological foundations for statistical theory.
Nonresponse Bias Analysis in Longitudinal Educational Assessment Studies

Abstract
Longitudinal studies are subject to nonresponse when individuals fail to provide data for entire waves or particular questions of the survey. We compare approaches to nonresponse bias analysis (NRBA) in longitudinal studies and illustrate them in the Early Childhood Longitudinal Study, Kindergarten Class of 2010-11 (ECLS-K:2011). Wave nonresponse with attrition yields a monotone missingness pattern, and we discuss weighting and multiple imputation (MI) approaches to NRBA for monotone patterns when the missingness mechanism is assumed missing at random (MAR). Weighting adjustments are effective when the constructed weights are correlated to the survey variable of interest. MI includes incomplete variables into the sequential or joint imputation model, yielding more efficient estimates when the variables are predictive of the survey outcome. Multilevel models with maximum likelihood estimation and marginal models via generalized estimating equations can also handle incomplete longitudinal data. We add offsets in the MI results as sensitivity analyses to assess missing not at random deviations from MAR. We conduct NRBA for descriptive summaries and analytic model estimates and find that in the ECLS-K:2011 application NRBA yields minor changes to the substantive conclusions. The strength of evidence about our NRBA is based on the strength of the relationship between the characteristics in the nonresponse adjustment and the key survey variables, so the key to a successful NRBA is to include strong predictors.

Keywords: Weighting, multiple imputation, sensitivity analysis, maximum likelihood estimation, generalized estimating equations.
1. Introduction

Nonresponse bias has become a methodological severe issue in sample surveys because of rapidly decreasing response rates (de Leeuw, Hox, and Luiten, 2018). Cross-sectional surveys are subject to unit nonresponse, where individuals fail to respond to the survey because of noncontact or refusal, and item nonresponse, where individuals fail to respond to particular questions that are sensitive or difficult to answer. In longitudinal panel surveys, an additional source of missing data is wave nonresponse, where some individuals fail to provide data for entire waves of the survey, because they are out of contact or not available to interview, attrition, or subsampling by design in follow-up studies.

This work responds to a request from the U.S. National Center for Education Statistics to create exemplars of nonresponse bias analysis (NRBA) to guide survey analysts. The previous work provided a ten-step exemplar for addressing NRBA in cross-sectional surveys (Si et al., 2022):

1) Analyze missing-data patterns.

2) Identify key survey variables and associated analyses.

3) Model key survey variables as a function of fully observed predictors.

4) Seek strong observed predictors in auxiliary data.

5) Model unit nonresponse as a function of observed predictors.

6) Assess observed predictors for the potential for bias adjustment.

7) Assess the effects of nonresponse weighting adjustments on key survey estimates.

8) Compare the survey with external data using summary estimates of key survey variables.
9) Perform a sensitivity analysis to assess the impacts of deviations from the assumption of missing at random (MAR).

10) Conduct item nonresponse bias analyses for all analyzed variables.

A critical feature is to characterize the strength of evidence about nonresponse bias contained in these NRBA indices, based on the strength of the relationship between the characteristics in the nonresponse adjustment and the key survey variables of interest (Little and Vartivarian, 2005; Little, Carpenter, & Lee, 2022). In this article, we discuss approaches to handling nonresponse in longitudinal studies.

In one sense, missing data in longitudinal and cross-sectional surveys are similar; if the data from different waves of the survey are concatenated into one row for each survey unit, with a set of columns for each of the waves – sometimes called the “wide view” of the data – then the missing data create a multivariate pattern of missing data, similar to what might be obtained for cross-sectional data with both unit and item nonresponse. The main differences are that the number of variables may be much greater when variables are repeatedly measured across waves, and longitudinal models such as growth models are of particular interest (Muthén, 2004). The availability of open-source software to fit such models when some of the repeated measures are missing is an additional feature that is not relevant to cross-sectional surveys.

A common approach to missing data is complete-case analysis, where analysis is restricted to individuals who respond to all the waves of the survey. This approach does not exploit information in the incomplete cases and can result in bias when the reasons for missing data depend on values of the study measures. Our approach to NRBA is to compare inferences for questions of interest based on alternative approaches to adjusting for nonresponse, including
weighting, multiple imputation (MI; Rubin, 1987), multilevel models with maximum likelihood (ML) estimation (e.g., Fitzmaurice, Davidian, Verbeke & Molenberghs, 2009) and marginal models via generalized estimating equation (GEE; Liang & Zeger, 1986) approaches for repeated measures, and sensitivity analysis to assess the impact of deviations from MAR, which is required by standard approaches. The basic premise is that if inferences are similar under the alternative approaches, then nonresponse bias is not a major concern.

We apply methods to data from the Early Childhood Longitudinal Study, Kindergarten Class of 2010–11 (ECLS-K:2011; Tourangeau, et al., 2013). The ECLS-K:2011 followed a cohort of children from their kindergarten year (the 2010–11 school year, referred to as the base year) through the 2015–16 school year, when most of the children were in the fifth grade. The ECLS-K:2011 study involves a multi-stage probability design, sequentially selecting geographic areas (counties or groups of contiguous counties) as primary sampling units, schools, and children to collect national data on children’s home and school experiences, growth, and learning. During the 2010–11 school year, when both a fall and a spring data collection were conducted, approximately 18,170 kindergartners from about 1,310 schools and their parents, teachers, school administrators, and before- and after-school care providers participated in the study. Fall and spring data collections were also conducted during the first- and second-grade years, where the fall collection was conducted with children in one-third of the sample selected for the study. In the third, fourth, and fifth grades, a spring data collection was conducted with the entire sample of children who participated in the base year. The study followed students who moved away from their original base-year schools after the spring base-year data collection, to their new schools. Some movers were followed with certainty, and others were followed for a subsample. The sample sizes in the follow-up waves decreased because of the mover
subsampling and attrition, which could also result in systematic differences in children assessment outcomes between the study participants and the target population. We apply an NRBA to evaluate the impact of nonresponse on child assessments in the analysis of the longitudinal ECLS-K:2011 study.

We focus on the descriptive summaries and mixed-effect model regression estimates. Estimates of subgroup means, such as average assessment scores across race/ethnicity and poverty groups, are of interest to policymakers. Education researchers are also interested in estimating growth curves representing trajectories of child development across time while considering the correlation between repeated measurements.

2. Background

Suppose the study collects baseline measures \((X_0, Y_0)\) and the number of \(T\) follow-up measures of the study variables \((X_t, Y_t)\), for \(t = 1, ..., T\), where the analysis of interest focuses on the descriptive summaries of the outcome \(Y\) and the regression of \(Y\) on the covariates \(X\) across \(T\) waves. In addition to the time-varying covariates \(X\), time-invariant covariates \(Z\) are also available, such as the base-year sample design features, survey administrative information, and other auxiliary variables collected at baseline. A complete case has all information of \((Z, X_0, X_1, ..., X_T, Y_0, Y_1, ..., Y_T)\) observed. Individuals dropping out between waves \(t - 1\) and \(t\) have \((Z, X_0, X_1, ..., X_{t-1}, Y_0, Y_1, ..., Y_{t-1})\) observed but \((X_t, ..., X_T, Y_t, ..., Y_T)\) missing. For participants who miss a wave and return to the study later, the missingness is intermittent. Along with unit and wave nonresponses, item nonresponse arises when participants only provide answers to a subset of the survey variables \((X_0, X_1, ..., X_T, Y_0, Y_1, ..., Y_T)\).
The missingness mechanism refers to the relationship between missingness and the survey variables, and plays a crucial role in NRBA. Rubin (1976) and Little (2021) treated the response indicators $R$ as random variables and characterized the missingness mechanism by the conditional distribution of $R$ given the data. If the response indicator $R$ does not depend on any values of the data, the missingness is missing completely at random (MCAR). MCAR is a strong and often implausible assumption. A weaker assumption is MAR, where the missingness depends only on values of observed variables. If missingness depends on missing variables after conditioning on the observed variables, the data are called missing not at random (MNAR). The MAR assumption is untestable from the collected data alone without additional structural assumptions, so in our NRBA we assess the sensitivity of inferences to deviations from MAR.

3. **NRBA methods for a monotone missingness pattern.**

In the ECLS-K:2011 study, as in many longitudinal studies, the pattern of missing data is predominantly monotone, such that individuals dropping out at wave $t$ do not reenter the study in a later wave. Therefore, we focus here on methods suitable for a monotone pattern. The extensions to non-monotone dropouts are discussed in Section 5. Let $R_t$ denote the response indicator at wave $t$, where $R_t = 1$ if $(X_t, Y_t)$ is observed, otherwise $R_t = 0$ if the individual drops at wave $t$. For the monotone pattern, the response indicators in later waves will all be 0, i.e., $R_{t+1} = \cdots = R_T = 0$ if $R_t = 0$, and we have $\Pr(R_t = 0) = \Pr (R_t = R_{t+1} = \cdots = R_T = 0)$ and $\Pr(R_t = 1) = \Pr (R_t = R_{t-1} = \cdots = R_1 = 1)$.

The bias of an analysis depends on how the incomplete data are analyzed. A default approach to the analysis of longitudinal data with missing data is unadjusted complete-case analysis, where cases that are not complete over all waves are dropped, and the analysis of
complete cases may include sampling weights but does not adjust for nonresponse arising from attrition after baseline. This analysis yields consistent estimates if missingness depends on fully-observed baseline variables, but conditional on those variables, does not depend on repeated measures post-baseline.

The main approaches to reducing nonresponse bias from this default complete-case analysis (CCA) are (a) to estimate nonresponse weights that multiply the sampling weights in CCA; and (b) to impute the missing values, using MI combining rules to propagate imputation error in the inferences. We can also fit a model to the complete and incomplete data, i.e., available data, using a method that allows for missing data in the repeated measures. Weighting and imputation can also be applied to the available-case analysis (ACA), which is often used in practice. In Sections 3.1-3.3 we describe the main features of each of these approaches, assuming missingness is MAR. In Section 3.4 we describe a sensitivity analysis to assess deviations from MAR.

3.1 Weighting

Weighting is a common method of unit/wave nonresponse adjustment, with weights defined as the inverse of estimated response propensities. These can be estimated as the inverse of the response rates in adjustment cells formed from variables observed for respondents and nonrespondents, also known as weighting classes, or more generally by regressing response indicators on covariates, and creating weights that are the inverse of the estimated response probabilities from the regression. In longitudinal studies, different weights can be created depending on the set of complete cases being analyzed. For example, in the ECLS-K:2011 study, different weights are constructed based on the questions answered by children, parents, teachers,
and schools. In AC analyses, wave-varying follow-up weights could use the weights at baseline or in the previous wave as the starting point to adjust for nonresponse across waves. Suppose we are constructing weights for wave $t$ and assume MAR applies to all nonresponse mechanisms at each wave. A standard set of weights based on the baseline covariates are inverses of the estimated response propensity given the baseline information,

$$\hat{w}_t^{base} = P r^{-1}(R_t = 1|Z,X_0,Y_0).$$

(1)

An alternative approach, which makes better use of available data, expresses the response probability as a product of conditional probabilities given response at previous waves. These conditional probabilities can then condition on all available information in earlier waves. That is,

$$\hat{w}_t^{seq} = P r^{-1}(R_t = 1|Z,X_0,Y_0,X_1,Y_1,...,X_{t-1},Y_{t-1})$$

(2)

$$= P r^{-1}(R_t = R_{t-1} = ... = R_1 = 1|Z,X_0,Y_0,X_1,Y_1,...,X_{t-1},Y_{t-1})$$

$$= P r^{-1}(R_1 = 1|Z,X_0,Y_0) P r^{-1}(R_2 = 1|R_1 = 1,Z,X_0,Y_0,X_1,Y_1) ...$$

$$... P r^{-1}(R_t = 1|R_1 = 1,...,R_{t-1} = 1,Z,X_0,Y_0,X_1,Y_1,...,X_{t-1},Y_{t-1}).$$

Here we have $\hat{w}_t^{seq} = \hat{w}_{t-1}^{seq} * P r^{-1}(R_t = 1|R_1 = 1,...,R_{t-1} = 1,Z,X_0,Y_0,X_1,Y_1,...,X_{t-1},Y_{t-1}).$

In practice, the weights $\hat{w}_t^{base}$ or $\hat{w}_t^{seq}$ are scaled to sum to the available sample size at wave $t$.

Approaches to modeling the response propensities $P r(R_t = 1|\cdot)$, include parametric models such as logistic regressions and machine learning algorithms such as tree-based methods (e.g., Breiman et al., 1984; Buskirk & Kolenikov, 2015; Lohr, Hsu, & Montaquila, 2015).

With the constructed weights, population means are estimated by weighted sample means, regression coefficients from weighted regression models, and in the longitudinal setting, weighted multilevel models or weighted GEE (Robins, Rotnitzky, & Zhao, 1995). Sampling
variability can be accounted for by using resampling approaches, such as jackknife or bootstrap replication (Natarajan et al., 2008).

3.2 Multiple imputation
Weighting construction requires that covariates used in the response propensity modeling are fully observed; however, in practice item nonresponse could occur to both the outcome and covariates. Imputation of missing data is a feasible and attractive approach. To propagate the uncertainty of the imputation model, MI can be applied to simultaneously handle unit and item nonresponse. MI applies either joint or sequential conditional imputation models to generate multiple completed datasets. Inferences are obtained from multiple datasets by applying combining rules, which are approximations of Bayesian inference. To achieve inferential validity, the specified imputation models have to be proper and yield plausible imputations, and the imputation model and the analysis model need to be congenial (Xie & Meng, 2017). The imputation model can include auxiliary variables not included in the analysis model of interest, or variables available for imputation but not available in public use files for confidentiality concerns. Flexible models involving splines of the response propensity can be used to limit model misspecification and improve prediction accuracy (Zheng & Little, 2003).

With a monotone dropout pattern in longitudinal studies, we can sequentially impute missing responses from the first follow-up to the last wave, i.e., working with the wide data format where variables from each wave are concatenated into a single row for each individual in the sample:
\[ f(X_1, Y_1 | Z, X_0, Y_0) \rightarrow f(X_2, Y_2 | Z, X_0, Y_0, \hat{X}_1, \hat{Y}_1) \rightarrow \]

\[ \ldots f(X_T, Y_T | Z, X_0, Y_0, \hat{X}_1, \hat{Y}_1, \ldots \hat{X}_{T-1}, \hat{Y}_{T-1}). \]

Iteration or iterative imputation is not needed for monotone data. An alternative imputation strategy is to fit a multilevel model with individuals as clusters and repeated measurements as units with the long data format. A two-level imputation approach explicitly models the relationship between the survey outcome and time-varying covariates including the wave indicators and is available in the R packages, such as mice (Van Buuren & Oudshoorn, 1999). We use \((X_{it}, Y_{it})\) to denote the survey variables collected for individual \(i\) at wave \(t\), for \(i = 1, \ldots, n\), and \(t = 0, 1, \ldots, T\). The imputation model accounts for the correlation between repeated measures of the same individual over time by introducing varying effects across individuals.

\[ Y_{it} = \alpha_i + \beta_i X_{it} + \epsilon_{it}, \quad \alpha_i \sim N(\alpha, \sigma_{\alpha}^2), \quad \beta_i \sim N(\beta, \sigma_{\beta}^2), \quad \epsilon_{it} \sim N(0, \sigma^2). \] (4)

Here the example includes varying intercepts \(\alpha_i\) and varying coefficients \(\beta_i\) across individuals with overall means \((\alpha, \beta)\) and between-individual variances \((\sigma_{\alpha}^2, \sigma_{\beta}^2)\), and the error between repeated measures presents the within-individual variance \(\sigma^2\).

The imputation model can also accommodate response indicators and jointly model the missing values and missingness mechanisms \(f(X_t, Y_t, R_t)\) via selection models

\[ f(R_t | X_t, Y_t) f(X_t, Y_t), \text{ pattern mixture models } f(X_t, Y_t | R_t) f(R_t), \text{ and shared parameters } \]

\[ f(R_t | b_t) f(X_t, Y_t | b_t) f(b_t), \text{ i.e., conditional independence given a shared and unknown quantity } \]

\(b_t\) (Little & Rubin, 2019). MI can thus handle MAR and MNAR (e.g., Si, Reiter, & Hillygus, 2015, 2016; Si, Palta, & Smith, 2020); however, existing MI software usually assumes MAR.

3.3. \textit{Repeated measures models that allow for missing data}
An alternative to weighting and MI is to fit a model to the available data, using a method that allows for missing data in the repeated measures, with parameters estimated by GEE, ML or Bayesian methods. Applying GEE without nonresponse weights generally yields consistent estimates if missingness does not depend on the repeated measures, which is usually a strong assumption. Weighted GEE, including nonresponse weights, can produce valid inferences under weaker MAR assumptions. ML estimates maximize the incomplete data likelihood based on the analysis model. For example, in growth modeling, random effects are used to capture individual differences in development. Alternatively, under a latent variable modeling framework, structural equations models treat random effects as continuous latent variables (also known as growth factors), as in Mplus software (Muthén & Muthén, 2017). Weighted ML estimates maximize the pseudo-likelihood function, which weights each individual contribution to the likelihood by the inverse of the power of its estimated response propensity. ML under a repeated-measures model is asymptotically equivalent to MI under that model, and hence is likely to achieve similar results unless the sample size is small (Little & Rubin, 2019). An advantage of MI over ML is the ability to condition on auxiliary variables in the imputation model that are predictive of the missing values and are not included in the analysis model, thus potentially weakening the MAR assumption and improving precision.

### 3.4 Sensitivity analysis

The methods reviewed in the previous sections assume MAR, which is an untestable assumption. Accordingly, we propose and implement a sensitivity analysis to assess the impact of MNAR deviations from MAR.
Following the approach in Giusti and Little (2011), we apply an offset to MAR
imputations to model departures from MAR. For example, in an analysis of racial and ethnic
differences, we assume:

\[ E(Y_{it} | Z_t, X_{it}, R_{it} = 0) = E(Y_{it} | Z_t, X_{it}, R_{it} = 1) + k_t \cdot \sigma_{race/eth[i]}. \] (5)

Here the offset \( k_t \cdot \sigma_{race/eth[i]} \) is the product of the pre-specified \( k_t \) at the time point \( t \) of
dropout and the residual standard deviation for respondents stratified by race/ethnicity, where
\( race/eth[i] \) denotes the race/ethnicity category of the individual \( i \). The approach is implemented
as follows:

1. Run MAR-based MI.
2. If individual \( i \) drops out of the study at time \( t \), fit the regression model \( (Y_{it} | R_{it} = 1, -) \)
   conditional on all other available information up to this wave and obtain the residuals.
3. Calculate the residual standard deviation for respondents stratified by race/ethnicity and
   obtain \( \sigma_{race[i]} \).
4. With the pre-specified value of \( k_t \), add \( k_t \cdot \sigma_{race[i]} \) to the missing data at time \( t \) and
   obtain the imputed value \( \hat{Y}_{it} \).
5. Conditional on the imputed value \( \hat{Y}_{it} \), continue the MAR-based MI for \( \hat{Y}_{i,t+1} \), and so on.

We try different pre-specified values of \( k_t \) as sensitivity analysis. Giusti and Little (2011)
consider 0.8, 1.2 and 1.6 to reflect small, medium, and large deviations from MAR, respectively.
Here we use -0.8, -1.2 and -1.6, assuming that nonrespondents have lower assessment outcomes
than those of respondents.
4. **Application to the Early Childhood Longitudinal Study**

We focus on the spring data collections in the ECLS-K:2011 study and examine the child growth across the kindergarten and fifth grade, i.e., with the kindergarten year referred to as the base study \((t = 0)\) and five follow-up waves \((t = 1, \ldots, T(= 5))\). We estimate descriptive summaries and developmental trajectories of the child assessment performances and examine the disparity across subgroups with different race/ethnicity, sex, and poverty categories. The assessment outcome is the item response theory (IRT)-based overall scale score for each domain, such as reading and mathematics, specifically the sum of the predicted probabilities that the child would have correctly answered each assessment item. We include child-level characteristics, namely sex, age, race/ethnicity, disability and special education status, family-level measures on poverty, socioeconomic and food security status, and school-level characteristics, including the school type (public or private), region, locality, enrollment, percent of non-white students, lowest and highest grades offered at the school. The analysis model is a (weighted) multilevel model with random intercepts to account for the correlation between repeated measures.

4.1 **Missingness pattern and mechanism**

The data are subject to unit and item nonresponse, mainly arising because of attrition from the sample, and the fact that only a subsample of children moving to different schools are followed. The complete cases are individuals who have participated in all follow-up studies and include 9,590 out of the total 14,730 children. The available cases are those who participated in at least one of the follow-up studies.
Figure 1. Unit and item response patterns in spring data collections (R: response; UnitNR: unit nonresponse; and ItemNR: item nonresponse).

Figure 2. Unit nonresponse rates over follow-up waves (with the base kindergarten year as the reference) across race/ethnicity groups (API: Asians, Native Hawaiians, and other Pacific Islanders; Non-Hisp: not Hispanic; and Other: more than one race, not Hispanic).

The wave nonresponse pattern, displayed in Figure 1, is close to monotone with scattered item nonresponse. The primary source of unit nonresponse is failure to follow up movers. The proportion of item nonresponse is small. We address the item nonresponse by imputation, and then consider different approaches to handling wave nonresponse. Figure 2 depicts the different wave nonresponse rates across race/ethnicity categories, indicating that the non-Hispanic Black and API children tend to miss the follow-up studies. Racial disparities are present in the response mechanism and potentially affect child development. Table 1 summarizes the different NRBA approaches that will be explored below.

4.2 Weighting

To construct the attrition-adjusted weights, we fit stepwise logistic regression models of the propensity to respond at each follow-up wave \( Pr (R_t = 1) \) conditional on either baseline information (CCA-attr-w and ACA-attr-w) or all available variables collected at baseline, in previous waves and the current wave (ACA-seq-attr-w). The base weight reflecting the unequal probability of sampling is included as a candidate in the response propensity models. As an alternative, we use tree-based methods and select the variables and their high-order interactions that are predictive of the response propensity. We apply default values of the complexity parameters in pruning tree size, often resulting in simple trees with few nodes, which can be modified to increase the complexity and prediction power. For our purpose of constructing weights to achieve a balance between bias and balance, we construct the sequentially adjusted weights based on the stepwise logistic regression and the baseline-adjusted weights with conditional inference tree methods implemented in the R package party (Hothorn et al., 2006,
Detailed outputs are given in the Appendix. The constructed weight is the product of the inverse of the predicted response propensities and the base weight.

The CCA shows that race/ethnicity, special education status, assessment outcome in kindergarten, poverty, food security status, school type, enrollment, locale, region, the proportion of non-white and the highest grade in the school affect the tendency to participate in all waves. As a measure of the predictive accuracy, the Area Under the Curve (AUC) is 0.64, indicating that the selected covariates have moderate power to predict the response propensity.

For monotone data, ACA is attractive compared to CCA because it makes better use of available information. The response indicator can use the previous wave or the baseline as the benchmark, yielding sequential and baseline adjustments, respectively. The sequential adjustment utilizes survey variables in the previous waves, which could be highly related to the response mechanism and survey outcome at the current wave and substantially improve the prediction. If the attrition pattern is intermittent, ACA is not an option unless imputation is used to create a monotone pattern; otherwise, CCA can be applied because all conditional information is fully observed. This is the current weighting practice implemented by the ECLS-K:2011 study. As shown in the outputs of logistic regression models (given in the Appendix) for the ACA response indicators, the survey variables in the previous waves are often selected, as well as the base and attrition-adjusted weights. The sequential ACA response propensity models yield five AUC values between 0.59 and 0.66, and the ACA adjustments to the base year have five AUC values around 0.66. The weight $\hat{w}_{t}^{seq}$ of ACA-seq-attr-w is the product of the inverse of a series of conditional response propensities, given in Equation (2), and the base weight. We trimmed the $\hat{w}_{3}^{seq}$ at wave 3 at its 95% quantile value to avoid an extreme maximum value.
Table 2. Summary of the base and attrition-adjusted weights for the five follow-up waves (all with mean =1). The upper bound of efficiency loss due to weighting \( \text{Loss}(w) \) is defined as \( c^2(w) = \text{var}(w) / \text{mean}^2(w) \), resulting in the design effect of \( 1 + c^2(w) \).

Note: Base-w: base weight; CCA-attr-w: attrition-adjusted weights accounting for the cluster structure by individuals with complete cases; ACA-attr-w#: attrition-adjusted, conditional on the baseline information, weights accounting for the cluster structure by individuals with available cases in the #th follow-up wave; ACA-seq-attr-w#: attrition-adjusted, conditional on the previous information, weights accounting for the cluster structure by individuals with available cases in the #th follow-up wave. All reported sample sizes are rounded to the nearest ten due to confidentiality concerns.

Table 2 summarizes the 12 sets of different weights, and their distributions are similar with slight differences. The maximum efficiency loss due to weighting, $\text{Loss}(w)$, is defined as the squared value of the coefficient of variation (CV): $\text{Loss}(w) = \text{cv}^2(w) = \frac{\text{var}(w)}{\text{mean}^2(w)}$, and 1+$\text{Loss}(w)$ gives the design effects on the variance inflation due to weighting, which is calculated.
assuming independence between weights and the survey variable (Kish, 1965). Little and Vartivarian (2005) recommend using mean squared error measures to reflect the weighting effect on the tradeoff between bias and variance, while $1+ \text{Loss}(w)$ serves the upper bound of the design effects. The efficiency loss is 33% for the CCA-attrition weight, around 28-29% for the sequentially adjusted ACA weights, and between 31–40% for the baseline adjusted ACA weights. Figure 3 shows that the collected outcome distributions do not substantially change across respondent groups defined by the weight quintiles, indicating that the outcome is weakly correlated with the weight, regardless of how it is calculated.

4.3. **Imputation and sensitivity analysis**

We conduct sequential conditional MI using *mice* (Van Buuren, 2012), tailoring the imputation models to the incomplete variable types: logistic regression models for binary variables (e.g., sex and school types), multinomial logistic regression models for nominal variables (e.g., race/ethnicity), ordinal logistic regression models for ordered variables (e.g., poverty levels, social-economic status), tree-based methods for non-normally distributed numeric variables (e.g., age and percent of non-white students), and predictive mean matching for the assessment outcome (e.g., reading IRT scores). We run 15 or 30 iterations for each imputation during every wave to achieve convergence. We save five completed datasets for inferences after MI. The number of completed datasets can be substantially increased given sufficient computational resources. In our application we find that the impact on inferences is small and five datasets are sufficient for our NRBA purpose.

During the sensitivity analyses, we add the pre-described offset values to the missing values at the time of dropout and carry on the sequential imputation as conditional MAR.
4.4 Nonresponse bias analysis

We present estimates of the average assessment scores and regression coefficients of interest in a multilevel regression model with varying intercepts across children. We compare the wave-specific averages for children with different sex, race/ethnicity, and poverty levels. We calculate the weighted mean estimates and use the Taylor Series approximation for the variance estimation, implemented in the R package survey (Binder, 1983; Lumley, 2020). This also applies to the MI estimates when we account for the base weights to obtain the weighted estimate and within-imputation variance. Then we use MI combining rules to yield the total variance including the between-imputation variance.

Table 3 gives the overall mean estimates of the reading IRT scores in comparison of the approaches for descriptive summaries listed in Table 2 and one randomly selected single imputation. Table 3 shows that both CCA and weighted CCA give the largest estimate, and the weights in CCA do not change the overall estimate. Including the available cases decreases the mean score, and the use of weights in ACA mounts the decrease. MI yields values between the ACA and CCA estimates. The CCA, ACA, and MI analyses have different sample sizes. Considering the monotone response pattern and increasing reading assessment scores across grades, ACA includes more observations from lower grades than CCA and thus decreases the overall mean score, and MI imputes the potential scores in higher grades for students who drop out and thus increases the mean value comparing to ACA. Nevertheless, the differences are not substantial. Weights slightly change the estimates since they are weakly related to the outcome variable. ACA has lower variances than CCA mainly due to more included samples. MI exploits covariates in the imputation model that are predictive of the missing values to improve efficiency.
Table 3. Overall mean estimates (Est) of reading assessment scores with reported standard errors (SE) and bounds of the 95% confidence intervals (Lower, Up).

and reduce bias. When we add offsets in MI, the estimates substantially decrease, indicating that the analysis is sensitive to deviations from MAR.

The same conclusions generally apply to the subgroup estimates in Figure 4 that depict the subgroup estimates for API students across grades. Across grades, MI tends to generate slightly lower assessment scores than ACA and CCA approaches.

Next, we present the NRBA for regression coefficients. We model the assessment outcome with selected child, family and school characteristics of interest and estimate the wave effects across race/ethnicity categories. The mean structure is specified as

$$E(Y_{it}) = \alpha_0 + \beta_1 AGEC_{it} + \beta_2 AGEC_{it}^2 + \beta_3 SEX_i + \tilde{\beta}_4 RACETH_i + \tilde{\beta}_5 POV_{it}$$

$$+ \beta_6 PNW_{it} + \beta_7 STY_{it} + \tilde{\beta}_8 WAVE_{it} + \tilde{\beta}_9 WAVE_{it} * RACETH_i.$$  

Here the covariates include the wave indicators $WAVE_{it}$, race/ethnicity indicator $RACETH_i$, and their two-way interaction $WAVE_{it} * RACETH_i$, in the adjustment of age $AGEC_{it}$ (standardized), the squared term of age $AGEC_{it}^2$, sex $SEX_i$, poverty $POV_{it}$, the proportion of non-white students in the school $PNW_{it}$ and school type $STY_{it}$.

To account for the correlation between repeated measures of the same student, we consider both multilevel models with random effects using ML estimation and marginal models using GEE. The multilevel model includes random intercepts $\alpha_i$ varying across children with a variance of $\sigma^2_\alpha$ and random errors $\epsilon_{it}$ with a variance of $\sigma^2$: $\alpha_i \sim N(0, \sigma^2_\alpha), \epsilon_{it} \sim N(0, \sigma^2)$, which uses ML estimates for ACA and weighted ML estimates when incorporating weights into the pseudo-likelihood, respectively. The analysis model after MI is the multilevel model.
Figure 5. Different wave effects on reading item response theory (IRT)-estimated scores across race/ethnicity groups based on complete case analyses and available case analyses, before and after weighting adjustments (API: Asians, Native Hawaiians, and other Pacific Islanders; Non-Hisp: not Hispanic; Other: more than one race, not Hispanic; CCA: complete case analysis; ACA: available case analysis; CCA-base weighted: base weighted analysis accounting for the cluster structure by individuals with complete cases; CCA-attrition weighted: attrition-adjusted weighted analysis accounting for the cluster structure by individuals with complete cases; ACA-base weighted: base weighted analysis accounting for the cluster structure by individuals with available cases; ACA-seq-attr-w: attrition-adjusted, conditional on the previous information, weighted analysis accounting for the cluster structure by individuals with available cases). SOURCE: U.S. Department of Education, National Center for Education Statistics, Early Childhood Longitudinal Study, Kindergarten Class of 2010-11, 2011-16 Spring.
Figure 6. Different wave effects on reading item response theory (IRT)-estimated scores across race/ethnicity groups based on generalized estimating equations (GEE) before and after weighting (API: Asians, Native Hawaiians, and other Pacific Islanders; Non-Hisp: not Hispanic; and Other: more than one race, not Hispanic).

Figure 7. Different wave effects on reading item response theory (IRT)-estimated scores across race/ethnicity groups based on multiple imputation and the inclusion of offsets (API: Asians, Native Hawaiians, and other Pacific Islanders; Non-Hisp: not Hispanic; Other: more than one race, not Hispanic; MI: multiple imputation with sequential wave by wave conditional imputation; MI-offset: sensitivity analysis with an offset $k_t \sigma_{race}$ added to the MI imputations, with different pre-specified values $k_t = -0.8, -1.2$ and $-1.6$).

We fit GEE with a pre-specified first-order autoregressive working correlation structure and weighted GEE to include the adjusted weights in the marginal model.

We present the estimates ($\vec{\beta}_B$, $\vec{\beta}_g$) in Figures 5–7. Different weighting approaches have negligible effects on coefficient estimates. Shown in Figure 5, the estimates are similar across the CCA, weighted CCA, ACA, and weighted ACA methods. Figure 6 compares the GEE and weighted GEE estimates, which are similar. GEE models use a different working correlation structure from the multilevel models, but the effect on coefficient estimates is small. Even though the descriptive summaries are slightly different, MI gives different coefficient estimates compared to the alternatives, given in Figure 7. Adding offsets to MI also changes the coefficient estimates, which is as expected, since the offsets depend on residual standard deviations across race/ethnicity groups. This shows that model fitting is sensitive to missing data mechanisms, not robust against model misspecification. Figures 5-7 do not include the standard error estimates (given in the Appendix). We use large-sample approximations in the variance estimation, except for weighted GEE. The pseudo-ML and weighted GEE need to be combined with resampling methods to account for the sampling uncertainty.

5. Conclusions and discussion

We compare weighting, MI, repeated measures models that allow for missing data, and sensitivity analysis approaches for NRBA in longitudinal studies. We consider complete cases, available cases, and potential outcomes as fully balanced data after imputation. Our NRBA focuses on the monotone response pattern, fits regressions of key survey outcomes and indicators of nonresponse on variables observed for both respondents and nonrespondents, compares
estimates with and without nonresponse weighting adjustments, and implements sensitivity analyses based adding offsets to MI results to assess the impact of deviations from MAR missingness. The NRBA of analytic inferences has different findings from that of descriptive summaries, where the latter is apparently affected by different adjustment approaches. All analyses can be carried out straightforwardly with standard statistical software. We provide our example R codes in the Appendix.

Overall, we do not find substantial evidence of nonresponse bias in the ECLS-K:2011 study, though modest differences present for several estimates, perhaps reflecting the high response rates across waves and the large proportions of movers who cannot continue the study, rather than attriters. However, lack of evidence of bias in the NRBA does not necessarily mean lack of bias; the key to a strong NRBA is the existence of a rich set of auxiliary variables that are highly predictive of the survey variables. The auxiliary variables are collected from baseline or previous waves, across child, family, and school levels, available for both respondents and nonrespondents. The evidence is generally weak in this application because the observed covariates are not strongly related to the survey outcomes, where the assessment scores themselves are estimates based on the IRT models and subject to additional estimation error. NRBA findings for other survey variables may differ. We focus here on mean estimates for the population and population subgroups and regression models. In either setting, the key to a strong analysis is the availability of strong auxiliary variables that are not predictors in the regression model of interest.

As regards future work, data integration of multiple sources can improve NRBA by providing better auxiliary information for nonresponse adjustment, and benchmark information for external validation. We focused on a monotone dropout, which is the predominant pattern in
the ECLS-K:2011 study; MI is one approach that can handle intermittent missingness patterns (e.g., Si, Palta, & Smith, 2020). Hybrid approaches are also possible, such as using MI to create a monotone pattern and then sequentially weighting the resulting imputed data sets. Given rapidly decreasing response rates, probability samples become vulnerable to nonresponse bias. Assessing and adjusting for this bias requires an external reference sample of high quality or population distributions of highly predictive variables in the NRBA.
