(Received: April 18, 2022)

Spin-orbit coupling plays an important role in understanding exotic quantum phases. In this work, we present a scheme to combine spin-orbital-angular-momentum (SOAM) coupling and strong correlations in ultracold atomic gases. Essential ingredients of this setting is the interplay of SOAM coupling and Raman-induced spin-flip hopping, engineered by lasers that couples different hyperfine spin states. In the presence of SOAM coupling only, we find rich quantum phases in the Mott-insulating regime, which support different types of spin textures such as spin vortex and nonrotating Mott core. Based on an effective exchange model, we find that these competing spin textures are a result of the interplay of Dzyaloshinskii-Moriya and Heisenberg exchange interactions. In the presence of both SOAM coupling and Raman-induced spin-flip hopping, many more-body phases appear, including canted-antiferromagnetic and stripe phases. Our prediction suggests that SOAM coupling could induce rich exotic many-body phases in the strongly interacting regime.

I. INTRODUCTION

Spin-orbit coupling, the interplay of particle’s spin and orbital degrees of freedom, plays a crucial role in various exotic phenomena in solid-state systems, such as the quantum spin Hall effect [1–4], topological insulators [5], and topological superconductors [6]. Ultracold atomic system, with high controllability degrees of freedom, is also a versatile candidate to investigate these quantum phenomena, by overcoming the problem of their neutrality [7]. One of these schemes relies on two-photon Raman transitions between two hyperfine states (pseudo-spin) of atoms [8], which are coupled with the atomic center-of-mass momentum [9]. Here, propagation directions of laser beams are crucial to determine the type of spin-orbit coupling in ultracold atoms. When two beams counter-propagate, atoms’ spin can be coupled with linear momentum of atoms, i.e. spin-linear-momentum coupling [12–17]. Rich exotic quantum states have been observed in ultracold atomic gases with spin-linear-momentum coupling [12–17].

Another fundamental type of spin-orbit coupling is called SOAM coupling. This coupling can be achieved by a pair of copropagating Laguerre-Gaussian (LG) lasers, where LG beam modes carry different orbital angular momenta along the direction of beam propagation [18]. The atomic system obtains orbital angular momentum from the copropagating LG beams via Raman transitions among the internal hyperfine states of atoms, whereas the transfer of photon momentum into atoms is suppressed [19, 20]. Within SOAM coupling, several intriguing quantum phases have been predicted theoretically [21–32] and observed experimentally [19, 20, 33, 34]. In these studies, however, interactions between atoms play tiny role in the various quantum phases, and one mainly focus on the weakly interacting regime.

In the paper, we combine SOAM coupling and strong correlations in ultracold gases, and focus on the response of spin degree of freedom to SOAM coupling. To achieve this goal, we propose a setup by introducing a beam with orbital angular momentum in the third direction (z direction) for a two-component ultracold bosonic gas loaded into a blue-detuned square lattice, as shown in Fig. 1. By controlling the frequency difference between the standing wave in the x direction and the Raman beam in the z direction, the two hyperfine states that match the Raman selection rules can be coupled, as shown in Fig 1(b). In this setup, we actually achieve both a SOAM coupling in the z direction [19, 20], and a Raman lattice in the x direction [35]. The competition between SOAM coupling and Raman-assisted spin-flip hopping may give rise to various quantum many-body phases.

This system can be effectively modeled by an extended Bose-Hubbard model for a sufficient deep optical lattice. We specifically consider the low-filling case with half filling in the Mott regime. To obtain many-body phases of the system, a bosonic version of real-space dynamical mean-field theory (RBDMFT) is implemented. Various competing phases are obtained in the Mott-insulating regime, including canted-antiferromagnetism, spin-vortex, and spin-vortex with nonrotating core. To explain the many-body phases, an effective spin-exchange model is derived, and we attribute these competing spin textures to the interplay of Heisenberg exchange and Dzyaloshinskii-Moriya interactions. Upon increasing the hopping amplitudes, atoms delocalize, and superfluid phases appear, including normal superfluid, rotating superfluid with vortex texture, and stripe superfluid phase.
Atoms along the $z$ direction, we choose an isotropic hard-wall box potential in $L_ω$, which can be approximated by the lowest-band Wannier function $|\psi\rangle$. Denotes the external trap potential in the $x$ direction.

The paper is organized as follows: in Section II, we introduce our setup with SOAM coupling, and the extended Bose-Hubbard model. In Section III, we give a detailed description of our RBDMFT approach. Section IV covers our results for our model. We summarize with a discussion in Section V.

II. MODEL AND HAMILTONIAN

We consider two-component bosonic gases trapped in a conventional two-dimensional (2D) square lattice. A plane-wave laser with orbital angular momentum $2l$ is added in the $z$ direction, as shown in Fig. 1(a). The two spin states are denoted as $σ = \uparrow$ and \downarrow, which are coupled by Raman transitions induced by the standing wave with Rabi frequency $Ω_1(r)$ in the $x$ direction, and the plane-wave laser with Rabi frequency $Ω_2(r)$ in the $z$ direction [35–38]. In the large detuning limit $Ω_{1,2} \ll |Δ|$, this system can be described by an effective single-particle Hamiltonian (see Appendix A) [26, 35]

$$\mathcal{H}_0 = \frac{p^2}{2m} - \frac{\hbar}{2mr^2}L_zσ_z + \frac{\hbar^2}{2mr^2} + V_{ext}(r) + \frac{δ}{2}σ_z + \Omega'(r)\cos kx \cdot σ_x,$$

where $L_z$ denotes orbital-angular-momentum operator of atoms along the $z$ direction, $δ$ the effective Zeeman field, and $\Omega'(r)\cos kx$ the periodic Raman field with $\Omega'(r) = Ω_1(r)Ω_2(r)$ being the effective Raman Rabi coupling. $V_{ext}$ denotes the external trap potential in the $x - y$ plane, where we choose an isotropic hard-wall box potential in the following.

For a sufficiently deep blue-detuned ($Δ > 0$) optical lattice, the single-particle states at each site can be approximated by the lowest-band Wannier function $\omega(\mathbf{x} - \mathbf{R}_j)$. In this approximation, the single-particle Hamiltonian (1) can be cast into a tight-binding model

$$\mathcal{H}_0 = -\sum_{\langle ij \rangle,σ} \left(t_σc^\dagger_{iσ}c_{jσ} + it_{ij}(c^\dagger_{iσ}c_{jσ} - c^\dagger_{iσ}c_{jσ}) + \text{H.c.}\right) + \sum_{i}(-1)^{iσ}Ω (c^\dagger_{iσ}c_{iσ+1} - c^\dagger_{iσ}c_{iσ-1} + \text{H.c.}) + \sum_{i}V_{\text{trap}}n_{iσ} + m_z(n_{i\uparrow} - n_{i\downarrow}),$$

where $\langle i, j \rangle$ denotes nearest neighbors between sites $i$ and $j$, and $δx$ is the site in the $x$ direction. $c^\dagger_{iσ}$ and $c_{iσ}$ are creation and annihilation operators for site $i$ and spin $σ$, respectively. $t_σ$ denotes conventional hopping amplitudes between nearest neighbors, $m_z$ the Zeeman field, $n_{iσ} = c^\dagger_{iσ}c_{iσ}$ the local density, and $V_{\text{trap}}$, the external trap with the contribution from centrifugal potential $\frac{\hbar^2}{2mr^2}$ being absorbed. $t_{ij}$ is the nearest-neighbor hopping induced by SOAM coupling, favoring hopping along the azimuthal direction (see Appendix B) [39–42]

$$t_{ij} = \int dx\omega^\ast(\mathbf{x} - R_i) \left(\frac{\hbar}{mr^2}L_z\right)ω(\mathbf{x} - R_j) \approx \left(\frac{x_iy_j - x_jy_i}{r^2}\right)t_{\text{soc}},$$

with $t_{\text{soc}} = -\frac{\hbar^2}{dm} \int dxω^\ast(x - d)\partial_xω(x).$ Here, $(x_i, y_i)$ are the coordinates of the $i$th site with the origin at the trap center, and $r'$ denotes the lattice spacing between the midpoint of sites $i$, $j$ and the origin. The Raman-assisted nearest-neighbor spin-flip hopping along the $x$ direction

$$Ω = \int dxΩ'(r)\omega^\ast(\mathbf{x} - R_i) [\cos kx]ω(\mathbf{x} - R_j),$$

where $Ω_{\uparrow\uparrow}$ and $Ω_{\downarrow\downarrow}$ denote the intra- and interspecies interactions, respectively. Additionally, we limit the present study to the situations when the interactions are repulsive and two hyperfine components are miscible with $U_{\uparrow\uparrow} = U_{\downarrow\downarrow} = 1.01U_{\uparrow\downarrow}$ and $t \equiv t_{\uparrow\downarrow} = t_{\downarrow\downarrow}$, which is a good approximation for two-hyperfine-state mixtures of $^{87}$Rb gas [43]. Thus, the total Hamiltonian of our system reads

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_\text{int} - \sum_{i,σ}μ_{σ}n_{iσ},$$

where $μ_{σ}$ is the chemical potential for component $σ$. Due to the competition between SOAM coupling and Raman-induced hopping, it is expected that various many-body phases develop in the strongly interacting many-body system described by Eq. (6). To resolve these quantum
phases, we apply real-space bosonic dynamical mean-field theory (RBDMFT), to obtain the complete phase diagrams. In the following, we set $U_{i\downarrow} = 1$ and optical lattice spacing $d = 1$ as the units of energy and length, respectively. We focus on the lower filling case with filling $n_i = n_i^\uparrow + n_i^\downarrow = 1$ in the Mott regime (the total particle number $N = \sum_i n_i = 330$), and the lattice size $N_{\text{lat}} = 24 \times 24$.

### III. METHOD

To resolve the long-range order, we utilize bosonic dynamical mean-field theory (BDMFT) to calculate many-body ground states of the system described by Eq. (6). By neglecting non-local contributions to the self-energy within BDMFT [44], the $N$-site lattice problem can be mapped to $N$ single-impurity models interacting with two baths, which correspond to condensing and normal bosons, respectively [45–48]. By a self-consistency condition, we can finally obtain the physical information of the $N$-site model. Note here that, in a real-space system without lattice-translational symmetry, the self-energy is lattice-site dependent, i.e. $\Sigma_{i,j} = \Sigma_i \delta_{ij}$ with $\delta_{ij}$ being a Kronecker delta, which motivates us to utilize a real-space version of BDMFT [49–51].

In RBDMFT, our challenge is to solve the single-impurity model, and the physics of site $i$ is given by the local effective action $S_{\text{imp}}^{(i)}$. Following the standard derivation [44], we can write down the effective action for impurity site $i$, which is described by

\[
S_{\text{imp}}^{(i)} = -\int_0^\beta d\tau d\tau' \sum_{\sigma,\sigma'} c_{\sigma}^{(i)}(\tau)^\dagger G_{\sigma\sigma'}^{(i)}(\tau - \tau')^{-1} c_{\sigma'}^{(i)}(\tau') + \int_0^\beta d\tau \sum_{\sigma,\sigma'} U_{\sigma\sigma'} n_{n_{\sigma}}^{(i)}(\tau) \left(n_{n_{\sigma}}^{(i)}(\tau) - \delta_{\sigma\sigma'}\right)
\]

\[
+ \frac{1}{z} \int_0^\beta d\tau \left( -\sum_{i,j,\sigma} t_{ij} \left(c_{\sigma}^{(i)}(\tau)^* \phi_{j\sigma}^{(i)}(\tau) + c_{\sigma}^{(i)}(\tau) \phi_{j\sigma}^{(i)}(\tau)^* \right) + it_{ij} \left(c_{\sigma}^{(i)}(\tau) \left(\phi_{j\sigma}^{(i)}(\tau)^* + \phi_{j\sigma}^{(i)}(\tau)\right) - c_{\sigma'}^{(i)}(\tau) \left(\phi_{j\sigma}^{(i)}(\tau)^* - \phi_{j\sigma}^{(i)}(\tau)\right)\right) \right) + \sum_{i,\sigma,\sigma' \neq \sigma} (-1)^1 \Omega \left(c_{\sigma}^{(i)}(\tau)^* \phi_{i\sigma}^{(i)}(\tau) - \phi_{i\sigma}^{(i)}(\tau) \phi_{i\sigma}^{(i)}(\tau)^*\right) + \sum_{i,\sigma,\sigma' \neq \sigma} V_{i\sigma} \left(n_{n_{\sigma}}^{(i)}(\tau) + m_\tau \left(n_{n_{\sigma}}^{(i)}(\tau) - n_{n_{\sigma}}^{(i)}(\tau)\right)\right).
\]

Here, $G_{\sigma\sigma'}^{(i)}(\tau - \tau')$ is a local non-interacting propagator interpreted as a dynamical Weiss mean field which simulates the effects of all other sites. To shorten the formula, the Nambu notation is used $c_{\sigma}^{(i)}(\tau) \equiv (c_{\sigma}^{(i)}(\tau), c_{\sigma}^{(i)}(\tau)^*)$. The parameter $z$ is the lattice coordination, which is treated as a control parameter within RBDMFT. The terms up to subleading order are included in the effective action. The static bosonic mean-fields are defined in terms of the bosonic operator $c_{\sigma}$ as

\[
\phi_{j\sigma}^{(i)}(\tau) = \left\langle \left. c_{j\sigma}^{(i)}(\tau) \right|_0 \right.,
\]

where $\langle ... \rangle_0$ means the expectation value in the cavity system without the impurity site.

Instead of solving the effective action directly, we normally turn to the Hamiltonian representation with the same effective action, i.e. Anderson impurity Hamiltonian [46, 52]. By exactly diagonalizing the Anderson impurity Hamiltonian with a finite number of bath orbitals [44, 53], we can finally obtain the local propagator

\[
G_{\sigma\sigma',\text{imp}}^{(i)}(\tau, \tau') = -\left\langle \left. Tc_{\sigma}^{(i)}(\tau) c_{\sigma'}^{(i)}(\tau')^\dagger \right|_0 \right.S_{\text{imp}}^{(i)}.\]

Next, we utilize the Dyson equation to obtain site-dependent self-energies in the Matsubara frequency representation

\[
\Sigma_{\sigma\sigma',\text{imp}}^{(i)}(i\omega_n) = G_{\sigma\sigma'}^{(i)}(i\omega_n)^{-1} - G_{\sigma\sigma'}^{(i)}(i\omega_n).
\]

In the framework of RBDMFT, we assume that the impurity self-energy $\Sigma_{\text{imp}}(i\omega_n)$ is local (momentum-independent) and coincides with the lattice self-energy $\Sigma_{\text{lattice}}(i\omega_n)$, whose assumption is exact in infinite dimensions and good approximations in higher dimensions [44]. Finally, we employ the Dyson equation in the real-space representation to obtain the interacting lattice Green’s function

\[
G_{\sigma\sigma',\text{lattice}}(i\omega_n) = \frac{1}{i\omega_n + \mu - \Sigma_{\text{imp}}(i\omega_n)},
\]

where boldface quantities denote matrices with site-dependent elements. $\varepsilon$ denotes a matrix with the elements being nearest-neighbor hopping amplitudes for a given lattice structure, $\mu$ represents the onsite hopping amplitudes with the external trap, and $\Sigma_{\text{imp}}(i\omega_n)$ denotes the self-energy. The self-consistency RBDMFT loop is closed by the Dyson equation to obtain a new local non-interacting propagator $G_{\sigma\sigma'}^{(i)}$. These processes are repeated until the desired accuracy for superfluid order parameters and noninteracting Green’s functions is obtained.
insulating regime with \( w \) serves as the driving term favoring three Mott phases with ferromagnetism (MI\(_{\text{I}}\)), spin-vortex (MI\(_{\text{II}}\)), and spin-vortex with antiferromagnetic core (MI\(_{\text{III}}\)). In the superfluid regime, two quantum phases appear with conventional superfluid (SF\(_{\text{I}}\)) and rotating superfluid (SF\(_{\text{II}}\)). Inset: winding number \( w \) as a function of \( t_{\text{soc}} \) with \( t = 0.015 \). (b) Contour plots of spin textures for phases MI\(_{\text{II}}\) and MI\(_{\text{III}}\) in the Mott-insulating regime. The interactions \( U_{\uparrow\uparrow} = U_{\downarrow\downarrow} = 1.01U_{\uparrow\downarrow} \).

**IV. RESULTS**

**A. Spin-orbital-angular-momentum coupling**

Before exploring the whole model, described by Eq. (6), we first discuss the competition between conventional nearest-neighbor hopping \( t \) and orbital-angular-momentum-induced hopping \( t_{\text{soc}} \). As shown in Fig. 2, the orbital-angular-momentum-induced hopping can be the order of the conventional one even for \( l = 1 \), where the hopping amplitudes are obtained from band-structure simulations [54]. By neglecting the Raman-induced spin-flip hopping \( \Omega \), Eq. (6) is reduced to

\[
H = - \sum_{\langle i,j \rangle,\sigma} \left( t_{\sigma\sigma} c_i^\dagger c_j + it_{ij}(c_i^\dagger c_{\bar{j}}^\dagger - c_i^\dagger c_{\bar{j}}) + \text{H.c.} \right) + \sum_{i,\sigma\sigma'} \frac{1}{2} U_{\sigma\sigma'} n_{i\sigma} (n_{i\sigma'} - \delta_{\sigma\sigma'}) + V_{\text{trap}} n_{i\sigma} - \mu_{i\sigma} n_{i\sigma},
\]

with \( m = 0 \).

As shown in Fig. 3, a many-body phase diagram is shown as a function of hopping amplitudes \( t \) and \( t_{\text{soc}} \) for interactions \( U_{\uparrow\uparrow} = U_{\downarrow\downarrow} = 1.01U_{\uparrow\downarrow} \), based on RB-DMFT. To distinguish quantum phases, we introduce superfluid order parameters \( \phi_{\sigma} \), pseudospin operators

\[
S_i^x = \frac{1}{2}(b_{i\uparrow}^\dagger b_{i\downarrow} - b_{i\downarrow}^\dagger b_{i\uparrow}), \quad S_i^y = \frac{1}{2}(b_{i\uparrow}^\dagger b_{i\downarrow} + b_{i\downarrow}^\dagger b_{i\uparrow}) \quad \text{and} \quad S_i^z = \frac{1}{2}(b_{i\uparrow}^\dagger b_{i\uparrow} - b_{i\downarrow}^\dagger b_{i\downarrow}),
\]

and winding number \( w = \frac{1}{2\pi} \sum_{\gamma} \arg(M_{\gamma}^* M_{\gamma}) \) with \( M_{\gamma} = S_{\gamma}^x + iS_{\gamma}^y \) and \( \gamma \) being a closed loop around the center of the trap [55, 56]. We observe five different quantum phases. When \( t_{\text{soc}} \ll t \), the system demonstrates ferromagnetic phase (MI\(_{\text{I}}\)), identical with the system without SOAM coupling. With the growth of \( t_{\text{soc}} \), a spin-vortex phase appears in the Mott-insulating regime with \( w = 0 \) (MI\(_{\text{II}}\)), since the growth of \( t_{\text{soc}} \) is equivalent to the growth of orbital angular momentum \( l \). As shown in Fig. 3(b), SOAM-induced spin rotation appears around the trap center with winding number \( w = 1 \), indicating that the spin rotates slowly with the corresponding response being mainly around the center of the trap. The physical reason is that the SOAM-induced hopping is site-dependent, and pronounced around the trap center, as indicated by Eq. (3). Further increasing \( t_{\text{soc}} \), the winding number \( w \) grows as well, as shown in the inset of Fig. 3(a), and finally we observe the whole system rotating in the regime \( t_{\text{soc}} \gg t \) (MI\(_{\text{III}}\)). Interestingly, this spin-vortex phase supports a nonrotating core of antiferromagnetic spin texture, with the nearest-neighbor spins being antiparallel in the trap center, as shown in Fig. 3(b).

To understand the underlying physics in the Mott regime, we treat the hopping as perturbations and derive an effective exchange model at half filling. With defining the projection operators \( P \) and \( Q = I - P \), we can project the system into the Hilbert space consisting of both singly occupied sites and the states being at least one site with double occupation, and obtain an effective
exchange model $H_{\text{eff}} = -\mathcal{P}H_z\mathcal{Q}(\frac{1}{\mathcal{Q}H_z\mathcal{Q}^-})\mathcal{Q}H_z\mathcal{P}$ [57–59]. The effective exchange model is finally given by:

$$H_{\text{eff}} = \sum_{\langle i,j \rangle} J_z S^z_i S^z_j + J (S^x_i S^x_j + S^y_i S^y_j) + D (S_i \times S_j)_z. \quad (13)$$

Here, $J_z = -4\left(\frac{2}{U_{\text{soc}}^2} - \frac{1}{U_{\text{soc}}^2}\right)(t^2 + t_{\text{soc}}^2)$, $J = -\frac{4(t^2 - t_{\text{soc}}^2)}{U_{\text{soc}}}$, and $D = -\frac{8t_{\text{soc}}}{U_{\text{soc}}}$. The details of derivation are given in the Appendix C.

In the effective model, a Dzyaloshinskii-Moriya term [60, 61] appears in the $z$ direction, induced by SOAM coupling. This term competes with the normal Heisenberg exchange interactions, resulting in a spin-vortex phase in the Mott-insulating regime. Interestingly, the Heisenberg exchange term $J$ also depends on the SOAM-induced hopping $t_{\text{soc}}$, and dominates in the regime $t_{\text{soc}} \gg t$, resulting an antiferromagnetic texture, which is consistent with our numerical results, as shown in Fig. 3(b).

With the increase of hopping amplitudes, atoms delocalize and the superfluid phase appears. We characterize the superfluid phase with superfluid order parameters $\phi_\sigma$ and winding number $w$. In the superfluid region, we observe two quantum many-body phases, with one being a phase with phase rotating (SF$_{\text{II}}$), and the other with conventional phase (SF$_1$).

### B. Interplay of spin-orbital-angular-momentum coupling and Raman-induced spin-flip hopping

Now we turn to study the whole system, described by Eq. (6), and focus on the stability of spin-vortex texture in the strongly interacting regime. Generally, SOAM coupling favors spin-vortex states and preserves rotational symmetry [24, 29], whereas the one-dimensional Raman-induced spin-flip hopping prefers the stripe phase and breaks translational symmetry [62, 63]. It is expected that more exotic many-body phases appear, due to the competition between SOAM coupling and Raman-induced spin-flip hopping. Here, we choose two hyperfine states of a $^{87}$Rb gas as examples, where all the Hubbard parameters are obtained from band-structure simulations [54]. To emphasize the influence of SOAM coupling, we consider the orbital angular momenta $l = 1$ and $l = 2$. Note here that $t \approx t_{\text{soc}}$ for orbital angular momentum $l = 1$ in the deep lattice, as shown in Fig. 2.

Rich phases are found in Fig. 4, including Mott-insulating phases with ferromagnetic (MI$_1$), vortex (MI$_{\text{II}}$), and canted-antiferromagnetic (MI$_{\text{IV}}$) orders [64], and superfluid phases with vortex (SF$_{\text{II}}$) and stripe (SF$_{\text{III}}$) textures. The interactions are $U_{\uparrow\uparrow}/U_{\uparrow\downarrow} = U_{\downarrow\downarrow}/U_{\uparrow\downarrow} = 1.01$, and the effective Zeeman field $m_z = 0$.

![Fig. 4](image_url)
V = 11.5 E_R with t ≈ 0.022 [Fig. 5(b)]. For smaller Ω, a spin-vortex phase develops with winding number w = 4 (MI_{II}). Increasing Ω, the spin texture changes to ferromagnetic (MI_I) and canted-antiferromagnetic (MI_{IV}) textures with vanishing winding number, which are characterized by magnetic spin-structure factor $S_q$, as shown in the inset of Fig. 5(a). We remark here that the MI_{IV} phase possesses spin-density-wave in $S_z$, ferromagnetic order in $S_x$, and antiferromagnetic order in $S_y$. The local phase of superfluid order parameter is shown in Fig. 5(b). For smaller Ω, a nonzero winding number of the local phase develops in the vortex superfluid phase. With Ω larger, we find the local phase demonstrates a stripe order instead.

To understand the physical phenomena in the Mott regime, we derive an effective exchange model of the system, described by Eq. (6), for filling $n = 1$

\[
H_{\text{eff}} = \sum_{\langle i,j \rangle} J_z^f S_i^x S_j^x + J_y^f S_i^y S_j^y + J_z^i S_i^z S_j^z + J_y^i S_i^y S_j^y + \sum_{\langle i,j \rangle} D (S_i \times S_j)_z ,
\]

where $J_z^f = -4 \left( \frac{(\langle \hat{I}^x \hat{I}^y \rangle - \frac{\Omega^4}{U_{11}})}{U_{11}} + \frac{\Omega^2}{11} - \frac{\Omega^2}{U_{22}} \right)$, $J_y^f = -4 \left( \frac{(\langle \hat{I}^z \hat{I}^y \rangle - \frac{\Omega^4}{U_{11}})}{U_{11}} + \frac{\Omega^2}{11} \right)$, and $J_y^i = -4 \left( \frac{(\langle \hat{I}^z \hat{I}^y \rangle - \frac{\Omega^4}{U_{11}})}{U_{11}} - \frac{\Omega^2}{U_{22}} \right)$.

We observe that the Raman-induced spin-flip hopping does not influence Dzyaloshinskii-Moriya interactions, but induce an anisotropy for Heisenberg exchange interactions in the $x$ and $y$ directions. When Ω is larger enough, the Raman-induced hopping can induce $J_y^i$ to be positive and $J_y^f$ negative. It indicates that a spin-density-wave and canted-antiferromagnetic order develops for larger Ω, consistent with our numerical results, as shown in Fig. 4. In the intermediate regime of Ω, the $J_y^i$ term dominates and a ferromagnetic order appears. For smaller Ω, the effective model reduces to Eq. (13), and the spin vortex pattern dominates.

In a realistic system, one can tune the balance of the two-spin components, which actually acts as an effective magnetic field $m_z$. Here, we can control the difference of chemical potential to study the effect of the magnetic field. In Fig. 6, we fix the depth of optical lattice $V = 9 E_R$ with hopping $t \approx 0.045$, and study the many-body phase diagram as a function of...
the effective magnetic field $m_z$ and Raman-induced spin-flip hopping $\Omega$. When the effective magnetic field is large and negative, the spin-$\downarrow$ component supports a vortex structure, indicated by the local phase of the superfluid order parameter, as shown in inset of Fig. 6, or vice versa. For large enough Raman coupling, the two components are mixed, and the system supports a stripe pattern in the $x$ direction. We remake here that the phase diagram is similar to the one achieved by the SOAM experiments in continuous space [20], where the difference is stripe order for larger Raman coupling, instead of vortex-antivortex pair phase [24, 29], since we essentially include a Raman lattice in the $x$ direction.

V. CONCLUSION AND DISCUSSION

In summary, we propose a scheme to investigate spin-orbital-angular-momentum coupling in strongly interacting bosonic gases in a two-dimensional square lattice. Using real-space dynamical mean-field theory, we obtain various quantum phases, including spin-vortex, canted-antiferromagnetic, ferromagnetic, and antiferromagnetic-core spin-rotating insulating phases. Based on effective exchange models, we find that the spin-vortex texture is a result of the Dzyaloshinskii-Moriya interaction, induced by spin-orbital-angular-momentum coupling. Due to the competition of Dzyaloshinskii-Moriya and Heisenberg exchange interactions, various spin textures develop. In the superfluid, we find three quantum phases with conventional, stripe and vortex orders, characterized by the local phase of superfluid order parameters. Our study would be helpful to identify interesting many-body phases in future experiments.

VII. APPENDIX

A. Single-particle Hamiltonian

In our scheme, the Raman transition is $\Lambda$-type configuration with $\Omega_1(r) = \Omega_1\cos(kx)$ along the $x$ direction and $\Omega_2(r) = \Omega_2e^{-2r^2/\rho^2}e^{-i2l\phi}$ along the $z$ direction. In the regime $|\Delta| \gg \Omega_{1,2}$, the single-photon transition between the ground and excited states is suppressed. We can adiabatically remove the excited state, and the system is effectively regarded as two-ground-state mixtures coupled by two-photon Raman processes. Including the two-photon Raman processes, we can obtain an effective spin-$1/2$ Hamiltonian

$$H = \begin{pmatrix}
\frac{p^2}{2m} + \frac{\delta}{2} & \Omega'(r) \cos kx \cdot e^{-i2l\phi} \\
\Omega'(r) \cos kx \cdot e^{i2l\phi} & \frac{p^2}{2m} - \frac{\delta}{2}
\end{pmatrix},$$

(S1)

where $\delta$ is a two-photon detuning, and $\Omega'(r) = \Omega_1\Omega_2e^{-2r^2/\rho^2}/\Delta$ denotes the Raman Rabi frequency. After introducing the unity transformation to the single-particle wave function

$$U = \begin{pmatrix}
e^{-il\phi} & 0 \\
0 & e^{il\phi}
\end{pmatrix},$$

(S2)

and Pauli matrix $\sigma$, we finally obtain

$$H = -\frac{\hbar^2}{2mr} \frac{\partial}{\partial r} \left( \frac{\partial}{\partial r} \right) + \frac{\delta}{2} \sigma_z + \frac{(L_z - ih\sigma_z)^2}{2mr^2} + \Omega'(r) \cos kx \cdot \sigma_x,$$

(S3)

where $L_z = -ih\partial_z$ is the orbital angular momentum along the $z$ axis. Normally, the plan-wave laser is a LG beam with the intensities being suppressed near the trap center, which can influence experimental observations. Here, we instead consider a Gaussian-type Raman beam with orbital angular momentum, where such a Gaussian beam can be obtained by a quarter-wave plate [S30, S66]. The waist of the plane-wave laser is set to $\rho = 20$. 

[557x756]7
FIG. S1. (Color online) Schematic for a $4 \times 4$ lattice. $C$ is the trap center, and $r_i (r_j)$ is the distance between site $i (j)$ and the trap center $C$, with $d$ being the lattice constant.

B. Orbital angular momentum in the Wannier basis

The angular momentum $t_{ij}$ is given by

$$H_{L_z} = \int dx \Psi^\dagger(x) \frac{i\hbar}{mr^2} L_z \Psi(x)$$

$$= \frac{i\hbar}{m} \int dx \Psi^\dagger(x) \frac{1}{r^2} L_z \Psi(x). \tag{S4}$$

For a sufficient deep lattice, the field operator $\Psi(x)$ can be expanded in the lowest-band Wannier basis $\omega(x - R_i)$. Eq. (S4) can be rewritten as

$$H_{L_z} = \frac{i\hbar}{m} \sum_{(i,j)} c_i^\dagger c_j \int dx^3 \omega^* (x - R_i) \frac{1}{r^2} L_z \omega (x - R_j). \tag{S5}$$

For nearest neighbors $i$ and $j$, we have the relation that

$$\frac{1}{r_1^2} K_{i,j} < \int dx^3 \omega^* (x - R_i) \frac{1}{r^2} L_z \omega (x - R_j) < \frac{1}{r_2^2} K_{i,j}, \tag{S6}$$

where $r_1 = \max(r_i, r_j)$, and $r_2 = \min(r_i, r_j)$, with $r_i (r_j)$ being the distance between site $i (j)$ and the trap center. For simplicity, we take the midpoint of site $i$ and $j$ as the approximation of $r$, and Eq. (S4) reads

$$H_{L_z} \approx \frac{i\hbar}{mr^2} \sum_{(i,j)} c_i^\dagger c_j K_{i,j}, \tag{S7}$$

with $K_{i,j} = \int dx^3 \omega^* (x - R_i) L_z \omega (x - R_j) = -i\hbar \int dx^3 \omega^* (x - R_i) (x\partial_y - y\partial_x) \omega (x - R_j)$. Generally, the Wannier function can be factorized into the $x$- and $y$-dependent parts for the deep lattice, and we finally obtain

$$K_{i,j} = -i\hbar \left( \int dx \omega^* (x - x_i) x w(x - x_j) \int dy \omega^* (y - y_i) \partial_y \omega (y - y_j) \right. \right.$$  

$$\left. - \int dx \omega^* (x - x_i) \partial_x \omega (x - x_j) \int dy \omega^* (y - y_i) y \omega (y - y_j) \right). \tag{S8}$$

For the discrete lattice system, $K_{ij}$ can be written in a product form

$$K_{i,j} = -i\hbar \left( \frac{x_i y_j - x_j y_i}{d} \right), \tag{S9}$$
with \( \alpha = \int dx \omega^* (x - d) \partial_x \omega (x) \) and \( d \) being the lattice constant, as shown in Fig. S1. We finally obtain the orbital angular momentum in the Wannier basis

\[
\mathcal{H}_{L_z} = \sum_{(i,j)} -i \frac{\hbar^2}{m \tau^2} x_i y_j - x_j y_i \left( c_i^\dagger c_j - c_j^\dagger c_i \right) \int dx \omega^* (x - d) \partial_x \omega (x)
\]

\[
= \sum_{(i,j)} \frac{x_i y_j - x_j y_i}{\tau^2} \left( -\frac{\hbar^2}{2m} \int dx \omega^* (x - d) \partial_x \omega (x) \right) \left( c_i^\dagger c_j - c_j^\dagger c_i \right).
\]

\[ (S10) \]

### C. Effective exchange model

The system can be described by an effective exchange model in the deep Mott-insulating regime. To derive the effective model, we first divide the Hilbert space according to site occupations for filling \( n = 1 \). We define the operators \( \mathcal{P} \) and \( \mathcal{Q} \), which denote the projection into the Mott state subspace \( \mathcal{H}_P \) and the perpendicular subspace \( \mathcal{H}_Q \). For a Hamiltonian \( \mathcal{H} \), the Schrödinger equation reads

\[ H |\psi\rangle = E |\psi\rangle. \]

(S11)

With the unity operator \( 1 = \mathcal{P} + \mathcal{Q} \), we obtain

\[ H(\mathcal{P} + \mathcal{Q}) |\psi\rangle = E(\mathcal{P} + \mathcal{Q}) |\psi\rangle. \]

(S12)

Multiplying by \( \mathcal{P} \) and \( \mathcal{Q} \) the left side of Eq. (S12) results in

\[ (\mathcal{P} \mathcal{H} \mathcal{P} + \mathcal{P} \mathcal{H} \mathcal{Q}) |\psi\rangle = E \mathcal{P} |\psi\rangle, \]

(S13)

\[ (\mathcal{Q} \mathcal{H} \mathcal{P} + \mathcal{Q} \mathcal{H} \mathcal{Q}) |\psi\rangle = E \mathcal{Q} |\psi\rangle. \]

(S14)

Eq. (S14) can be rewritten with the projector operator relation \( \mathcal{Q}^2 = \mathcal{Q} \),

\[ \mathcal{Q} |\psi\rangle = \frac{1}{E - \mathcal{Q} \mathcal{H} \mathcal{Q}} \mathcal{Q} \mathcal{H} \mathcal{P} |\psi\rangle. \]

(S15)

Inserting (S15) into (S13), we obtain an equation for \( \mathcal{P} |\psi\rangle \),

\[ (\mathcal{P} \mathcal{H} \mathcal{Q} \frac{1}{E - \mathcal{Q} \mathcal{H} \mathcal{Q}} \mathcal{Q} \mathcal{H} \mathcal{P}) \mathcal{P} |\psi\rangle = E \mathcal{P} |\psi\rangle. \]

(S16)

For Hamiltonian \( \mathcal{H} \), we can divide it into two parts \( \mathcal{H} = \mathcal{H}_t + \mathcal{H}_U \), where \( \mathcal{H}_t \) and \( \mathcal{H}_U \) are the hopping and interaction parts of \( \mathcal{H} \), respectively. Eq. (S16) can be rewritten as

\[ (\mathcal{P} \mathcal{H}_t \mathcal{Q} \frac{1}{E - \mathcal{Q} \mathcal{H}_U \mathcal{Q}} \mathcal{Q} \mathcal{H}_t \mathcal{P}) \mathcal{P} |\psi\rangle = E \mathcal{P} |\psi\rangle, \]

(S17)

with \( \mathcal{P} \mathcal{H}_U \mathcal{P} \), \( \mathcal{P} \mathcal{H}_Q \mathcal{P} \) and \( \mathcal{P} \mathcal{H}_t \mathcal{P} \) being zero. Because \( E \sim \frac{\tau^2}{\ell^2} \sim 0 \) in the Mott phase, we take \( \frac{1}{E - \mathcal{Q} \mathcal{H}_U \mathcal{Q}} \mathcal{Q} \mathcal{H}_t \mathcal{P} \approx \mathcal{Q} \mathcal{H}_t \mathcal{P} \). Using the expansion \( \frac{1}{x - B} = \sum_{n=0}^{\infty} (B x)^n \), with \( A = -\mathcal{Q} \mathcal{H}_U \mathcal{Q} \) and \( B = \mathcal{Q} \mathcal{H}_t \mathcal{Q} \), we finally obtain

\[ \mathcal{H}_{\text{eff}} = \mathcal{P} \mathcal{H}_t \mathcal{Q} \frac{1}{\mathcal{Q} \mathcal{H}_U \mathcal{Q}} \mathcal{Q} \mathcal{H}_t \mathcal{P} \mathcal{H}_t \mathcal{P}. \]

(S18)

Normally, we only need to include nearest-neighbor terms in the effective Hamiltonian with \( n = 0 \), i.e.

\[ \mathcal{H}_{\text{eff}} = \mathcal{P} \mathcal{H}_t \mathcal{Q} \frac{1}{\mathcal{Q} \mathcal{H}_U \mathcal{Q}} \mathcal{Q} \mathcal{H}_t \mathcal{P}. \]

(S19)

In the tight-binding regime, the subspace \( \mathcal{H}_P \) of the states with half filling for a two-site problem is

\[ \mathcal{H}_P : \{ |\uparrow\uparrow\rangle, |\uparrow\downarrow\rangle, |\downarrow\downarrow\rangle, |\downarrow\downarrow\rangle \}, \]

(S20)

where \( |\sigma, \sigma'\rangle \) denotes the spin state \( \sigma \) in the left site and \( \sigma' \) in the right one. The subspace \( \mathcal{H}_P \) for doubly occupied sites is

\[ \mathcal{H}_Q : \{ |\uparrow\uparrow\rangle, |\uparrow\downarrow\rangle, |\downarrow\downarrow\rangle \}. \]

(S21)
In a matrix form, \((\mathbf{QH}_U\mathbf{Q})^{-1}\) is given by

\[
(\mathbf{QH}_U\mathbf{Q})^{-1} = \begin{pmatrix}
\frac{1}{\Omega} & 0 & 0 \\
0 & \frac{1}{\Omega} & 0 \\
0 & 0 & \frac{1}{\Omega^2}
\end{pmatrix}.
\]  

(S22)

According to Eq. (S19), we obtain the final effective Hamiltonian

\[
\mathcal{H}_{\text{eff}} = -\left(\frac{4\left(t^2 + t^2_{ij}\right)}{U} + 2\Omega^2\right) (n_{i\uparrow}n_{j\downarrow} + n_{i\downarrow}n_{j\uparrow}) - \left(\frac{2\left(t^2 + t^2_{ij}\right)}{U_{\uparrow\downarrow}} + 4\Omega^2\right) (n_{i\uparrow}n_{j\downarrow} + n_{i\downarrow}n_{j\uparrow})
\]

\[
- 2\left(-t + it_{ij}\right)^2 c^\dagger_{i\uparrow}c_{i\downarrow}c^\dagger_{j\uparrow}c_{j\downarrow} - 2\left(-t - it_{ij}\right)^2 c^\dagger_{i\uparrow}c_{i\downarrow}c^\dagger_{j\downarrow}c_{j\uparrow}
\]

\[
- 2\Omega^2 c^\dagger_{i\uparrow}c_{i\downarrow}c^\dagger_{j\uparrow}c_{j\downarrow} + c^\dagger_{i\downarrow}c_{i\uparrow}c^\dagger_{j\downarrow}c_{j\uparrow} - (-1)^i \left(2\Omega(-t - it_{ij}) + \frac{2\Omega(-t - it_{ij})}{U_{\uparrow\downarrow}}\right) (c^\dagger_{j\downarrow}c_{j\uparrow} + c^\dagger_{i\downarrow}c_{i\uparrow})
\]

\[
= (-1)^i \left(\frac{2\Omega(-t + it_{ij})}{U_{\uparrow\downarrow}} + \frac{2\Omega(-t + it_{ij})}{U_{\downarrow\uparrow}}\right) (c^\dagger_{j\downarrow}c_{j\uparrow} + c^\dagger_{i\downarrow}c_{i\uparrow})
\]

(S23)

Introducing the pseudospin operator as follows

\[
S^x_i = \frac{1}{2} \left(c^\dagger_{i\uparrow}c_{i\downarrow} + c^\dagger_{i\downarrow}c_{i\uparrow}\right)
\]

(S24)

\[
S^y_i = \frac{1}{2i} \left(c^\dagger_{i\uparrow}c_{i\downarrow} - c^\dagger_{i\downarrow}c_{i\uparrow}\right)
\]

(S25)

\[
S^z_i = \frac{1}{2} (n_{i\uparrow} - n_{i\downarrow})
\]

(S26)

Eq. (S23) can be rewritten as

\[
\mathcal{H}_{\text{eff}} = -4 \left(\frac{2\left(t^2 + t^2_{ij}\right)}{U} + \Omega^2\right) S^x_i S^z_j - 4 \left(\frac{t^2 - t^2_{ij}}{U_{\uparrow\downarrow}} + \Omega^2\right) S^y_i S^z_j
\]

\[
- 4 \left(\frac{t^2 - t^2_{ij}}{U_{\uparrow\downarrow}} - \Omega^2\right) S^y_i S^z_j - 8\Omega t_{ij} (S^x_i S^z_j - (-1)^i \Omega t_{ij} \left(\frac{4}{U_{\downarrow\uparrow}}\right) (S^y_i - S^y_j).
\]

(S27)

The result can be easily extended to the case with vanishing \(\Omega = 0\), and it reads

\[
\mathcal{H}_{\text{eff}} = -4 \left(\frac{2\left(t^2 + t^2_{ij}\right)}{U} - \frac{t^2 + t^2_{ij}}{U_{\uparrow\downarrow}}\right) S^x_i S^z_j - 4 \left(\frac{t^2 - t^2_{ij}}{U_{\uparrow\downarrow}}\right) S^y_i S^z_j
\]

\[
- 4 \left(\frac{t^2 - t^2_{ij}}{U_{\uparrow\downarrow}}\right) S^y_i S^z_j - 8\Omega t_{ij} (S^x_i S^z_j).
\]

(S28)

In our simulations, the number of normal bath orbitals is $N_{\text{bath}} = 4$ with the maximum occupation number for each normal bath orbital $N = 2$. The Fock space is truncated at a maximum occupation number $N_{\text{fock}} = 5$.

In the band-structure simulations, we consider a system of ultracold $^{87}$Rb atoms with s-wave scattering length $a_{s}^{\uparrow\downarrow} \approx 100a_B$ and $a_{s}^{\uparrow\downarrow}/a_{s}^{\uparrow\uparrow} \approx 1.01$, with $a_B$ being the Bohr radius. To achieve a two-dimensional square lattice formed by standing-wave lasers with a wave length 738 nm, a strong confinement is assumed in the z direction with a depth $V_z = 100E_R$.
