Abstract

We present Pre-trained Machine Reader (PMR), a novel method to retrofit Pre-trained Language Models (PLMs) into Machine Reading Comprehension (MRC) models without acquiring labeled data. PMR is capable of resolving the discrepancy between model pre-training and downstream fine-tuning of existing PLMs, and provides a unified solver for tackling various extraction tasks. To achieve this, we construct a large volume of general-purpose and high-quality MRC-style training data with the help of Wikipedia hyperlinks and design a Wiki Anchor Extraction task to guide the MRC-style pre-training process. Although conceptually simple, PMR is particularly effective in solving extraction tasks including Extractive Question Answering and Named Entity Recognition, where it shows tremendous improvements over previous approaches especially under low-resource settings. Moreover, viewing sequence classification task as a special case of extraction task in our MRC formulation, PMR is even capable to extract high-quality rationales to explain the classification process, providing more explainability of the predictions.

1 Introduction

Span extraction, such as Extractive Question Answering (EQA) (Rajpurkar et al., 2016) and Named Entity Recognition (NER) (Tjong Kim Sang and De Meulder, 2003), is a family of Natural Language Understanding (NLU) tasks with the goal of detecting token spans according to certain requirements (e.g. task labels or questions). As depicted in the upper part of Figure 1, the common practice for achieving state-of-the-art span extraction performance leverages Pre-trained Language Models (PLMs) to build a discriminative model under the paradigm of Sequence Tagging or Machine Reading Comprehension (MRC) (Chen et al., 2017; Li et al., 2019, 2020; Zhang et al., 2022; Luo et al., 2022). Here the base PLMs could be pre-trained Masked Language Model (MLM) (e.g., BERT (Devlin et al., 2019)) or pre-trained Masked Sequence-to-Sequence model (MS2S) (e.g., BART (Lewis et al., 2020)). However, due to the different learning objectives and data formats between PLM pre-training and task-specific fine-tuning, the discriminative fine-tuning methods are insufficient to well adapt PLMs to downstream tasks when there is limited training data available, leading to poor low-resource extraction performance (Chada and Natarajan, 2021).

Prompt-based fine-tuning (Schick and Schütze, 2021a; Liu et al., 2021b) is a popular solution to mitigate the gap between pre-training and fine-tuning and achieves remarkable few-shot results
in various span extraction tasks (Cui et al., 2021; Chada and Natarajan, 2021; Lu et al., 2022). As shown in the middle part of Figure 1, by reformulating the downstream task as a masked language modeling problem, the PLMs in prompt-based fine-tuning are asked to generate response words to a given prompt, typically a task-specific template, as prediction. Despite its success, tackling extraction tasks in a generative manner may yield several disadvantages. Cui et al. (2021); Chen et al. (2022b) focus on generating label tokens (e.g., “person” for PER entities) of the desired spans and narrow down the search space to a smaller vocabulary of pre-selected label tokens, while fitting span extraction into this framework requires extensive prompt designs (Ma et al., 2022), greatly limiting its portability to other tasks/domains. When the desired predictions are target spans (e.g., the “answer” in EQA task), prompt-based methods have to autoregressively generate span tokens. Such a process usually requires the exploration of a large search space, and the output format still differs substantially from that of pre-training, i.e. grammatical phrase vs. randomly masked span (Chada and Natarajan, 2021; Lu et al., 2022).

To bridge the gap between pre-training and fine-tuning while not introducing the aforementioned disadvantages, we propose Pre-trained Machine Reader (PMR) as a retrofit of PLM\(^1\) for better span extraction. As shown in the bottom part of Figure 1, the proposed PMR resembles common MRC models to introduce an MRC head on top of PLMs, but it is enhanced with an MRC-style continual pre-training. During fine-tuning, by maintaining the same MRC-style learning objectives and data formats as pre-training, PMR allows efficient knowledge transfer and consequently shows great potential in low-resource scenarios. Note that as MRC has proved to be a universal paradigm (Hermann et al., 2015; Li et al., 2020; Liu et al., 2020; Wu et al., 2020; Keskar et al., 2020), our PMR can be directly applied to a broad range of span extraction tasks without additional task designs.

Specifically, we construct a large volume of general-purpose and high-quality MRC-style training data based on Wikipedia anchors (the hyperlinked texts). For each Wikipedia anchor, we fetch a pair of correlated articles: one provides detailed descriptions for the hyperlinked items (defined as home article in Figure 2), and the other mentions the specific anchor text (defined as reference article in Figure 2). Naturally, we can construct an MRC-style example where the anchor is the answer, the surrounding passage of the anchor in the reference article is the context, and the anchor entity’s definition in the home article is the query, refer to Figure 2 (a) for a concrete example. Then, we propose a novel task of Wiki Anchor Extraction (WAE), which first classifies whether the context and the query are relevant, and if so, asks the model to extract the answer from the context satisfying the query description. Note that, unlike previous multi-task fine-tuning methods that use the labeled data to retrofit PLMs (Khashabi et al., 2020; Aghajanyan et al., 2021), PMR only leverages the ubiquitous hyperlinks to create pre-training data, which is easier to scale up and guarantees better generalization capability. Such advantages are particularly important for domain-specific tasks or non-English languages with limited labeled data.

We evaluate the effectiveness of our PMR on two representative span extraction tasks: NER and EQA. Our PMR consistently obtains better span extraction results compared to vanilla PLMs and surpasses the best baselines by large margins under almost all of the few-shot settings (up to 6.3 F1 on EQA and 16.3 F1 on NER). Moreover, we also provide insightful analyses on more practical applications, such as out-of-domain generalization and multi-dataset learning. Meanwhile, viewing sequence classification task as a special case of extraction task in our MRC formulation, PMR is capable of extracting high-quality rationales, which contributes a lot to the explainability of the classification process (Chen et al., 2022a).

In summary, our contributions are as follows: (1) We construct a large volume of general-purpose and high-quality MRC-style training data to retrofit PLMs to PMRs. (2) By unifying pre-training and fine-tuning as the same discriminative MRC process, the proposed PMR obtains state-of-the-art results under all few-shot NER settings and 4 (out of 5) few-shot EQA settings. (3) PMR also shows encouraging potential in explaining the sequence classification process.

2 PMR: A Pre-trained Machine Reader

In this section, we describe PMR from the perspectives of model pre-training and downstream fine-tuning. For pre-training, we will first describe the curation procedure of large-scale MRC-style
data from Wikipedia, which frees the pre-training stage with any human annotations. We will also show a general architecture that unifies extraction tasks and describe how PMR is pre-trained with our Wiki Anchor Extraction (WAE) task. For fine-tuning, we present how PMR can seamlessly and uniformly tackle extraction tasks.

**Task Overview** Specifically, our PMR receives data in the format of \((Q, C; \{A^k\}_{k=1}^K)\), where \(Q\) is a natural language query, \(C\) is the input context and \(\{A^k\}_{k=1}^K\) are the answers to the query. Each answer is a contiguous token span in the context and we allow zero \((K = 0)\) or multiple \((K > 1)\) answers to suit diverse downstream NLU tasks.

2.1 Pre-training of PMR

**Pre-training Data Preparation** Training a PLM can be easily scaled on millions of raw texts with an MLM learning objective. While training PMR in the MRC paradigm requires labeled (query, context, answers) triplets as supervision signals, which is prohibitively expensive for large-scale pre-training. To remedy this limitation, we propose to automatically construct general-purpose and high-quality MRC-style training data with the help of Wikipedia anchors.

As illustrated in Figure 2 (a), a Wikipedia anchor hyperlink two Wikipedia articles: the home article that provides detailed descriptions of the anchor entity, i.e., “Silicon”, and the reference article where the anchor is mentioned. We leverage the large scale of such hyperlink relations in Wikipedia as the distant supervision to automatically construct the MRC triplets. Specifically, we regard an anchor as the MRC answer for the following context and query pair. Given the appearance of the anchor, the sentences surrounding it in the reference article would naturally serve as the MRC context. While the query contains the sentences from the first section of the home article, which usually composes the most representative summary for the anchor entity (Chang et al., 2020), such a query provides the MRC model with a precise definition of the anchor entity, and thus it can serve as the guidance for extracting answers (i.e., anchor text) from the context.

Concretely, we consider sentences within a window size \(W\) of the anchor as the MRC context, while for the query, we use the first \(T\) sentences from the home article. Using longer context and query can enable the encoder to learn richer semantics and handle downstream tasks with longer input. Note that the context may cover multiple mentions of the same anchor entity. In this case, we treat all of them as valid MRC answers (i.e. \(K > 1\)) so as not to confuse the model training. More importantly, it naturally resembles the multi-span extraction downstream tasks like NER. To avoid information leakage of the query as well as keep its grammar correctness, we substitute the text spans overlapped more than 50% with the anchor entity name to the word \(it\) in the query.

In addition to the positive MRC-style pre-training data described above, where the constructed query and context are linked by an anchor, we also construct negative examples by pairing a context with an irrelevant query, i.e., without the hyperlink association. With the help of negative
examples, the model should learn the ability to identify passage-level relevance, and thus not extract any answer (i.e. $K = 0$) from them.

**Model Pre-Training** Motivated by the success of formulating extraction tasks as MRC problems (Liu et al., 2020; Li et al., 2020), we take a step further to propose a unified architecture for both MRC pre-training and fine-tuning extraction tasks.

As shown in Figure 2 (b), PMR has two major components: an Encoder and an Extractor. The Encoder receives the concatenation of the query $Q$ and the context $C$ as the input $X$ and represents each input token into hidden states $H$:

$$X = [[\text{CLS}], Q, [\text{SEP}], C, [\text{SEP}]]$$

$$H = \text{Encoder}(X) \in \mathbb{R}^{M \times d}$$

(1)

where $[\text{CLS}]$ and $[\text{SEP}]$ are special tokens inserted into the sequence, $M$ is the sequence length, and $d$ is the dimension of the hidden states. The encoder $\text{Encoder}(\cdot)$ can denote any PLM for retrofitting, e.g. RoBERTa.

The Extractor receives the hidden states of any two tokens and predicts the probability score telling if the span between the two tokens should be output as an answer. We leverage a general way (Luong et al., 2015) to compute the score matrix $S$:

$$S = \text{sigmoid} (\text{FFN}(H)^T H) \in \mathbb{R}^{M \times M}$$

(2)

where $\text{FFN}$ is the feed-forward network (Vaswani et al., 2017), and $S_{i,j}$ is the probability to extract the span $X_{i:j}$ as output. Note that our general way avoids creating a large $\mathbb{R}^{M \times M \times 2d}$-shape tensor of the concatenation way (Li et al., 2020), consuming fewer resources for better training efficiency.

PMR is pre-trained with the WAE task which checks the existence of answers in the context and extracts them if there are. For the first goal, it determines whether the context contains text spans that are described by the query, i.e. the query can be answered by these spans:

$$L_{\text{cls}} = \text{CE}(S_{1,1}, Y_{\text{cls}})$$

(3)

where $\text{CE}$ is the cross-entropy loss, $S_{1,1}$ at $[\text{CLS}]$ token denotes the query-context relevance score, and $Y_{\text{cls}} = 1$ indicates they are relevant (i.e. answers exist). This task mimics the downstream situation where there is no span to be extracted in the context (e.g. NER), and encourages the model to learn through the semantic relevance of two pieces of text to recognize the unextractable examples.

For the second goal, the model is expected to extract all correct spans from the context as answers, which can be implemented by predicting the answer positions:

$$L_{\text{ext}} = \sum_{N<i<j<M} \text{CE}(S_{i,j}, Y_{\text{ext}})$$

(4)

where $Y_{i,j} = 1$ indicates that the span $X_{i:j}$ is an answer to $Q$, and $N$ is the positional offset of the context in $X$. Existing works (Chen et al., 2017; Li et al., 2020) also predict the start and end probabilities as two additional objectives, while we find that they are redundant for our matrix-based objective and also not compatible with multi-span extraction.

Finally, our overall training objective $L_{\text{wae}}$ is:

$$L_{\text{wae}} = L_{\text{cls}} + L_{\text{ext}}$$

(5)

Note that except used in Eq. 3 and 4, other portions of $S$ are masked when computing the loss.

### 2.2 Fine-tuning PMR on Extraction Tasks

As mentioned, most extraction tasks can be transformed into an MRC problem. Meanwhile, sequence classification can also be regarded as an extraction task in our MRC formulation and thus benefits from the extraction capability of PMR to extract rationales (refer to Sec. 6). Therefore, we unify both span extraction and sequence classification in our MRC formulation, which typically follows four categories: (1) span extraction with pre-defined labels such as NER: each task label is treated as a query to search its corresponding answers in the input text (context); (2) span extraction with natural questions such as EQA: the question is treated as the query for the given passage (context); (3) Sequence classification with pre-defined task labels such as sentiment analysis: each task label is used as a query for the input text (context); (4) Sequence classification with natural questions on multiple choices, such as multi-choice QA: we treat the question concatenated with one choice as the query for the given passage (context). Then in the output space, extraction-based problems (i.e. types (1) and (2)) are tackled via predicting $S_{i,j}$ related to context tokens for extracting the answer span $X_{i:j}$, and classification-based problems (i.e. types (3) and (4)) are tackled by conducting relevance classification on $S_{1,1}$ at the $[\text{CLS}]$ token (extracting

---

2Note that the task with sentence pair as input should be classified into type (3), where we treat the task label as the query and the concatenation of two sentences as the context.
if relevant). Refer to Appendix A.1 for the detailed formulation.

3 Experimental Setup

3.1 Wikipedia Data Pre-processing

We download the 2022-01-01 dump of English Wikipedia. For each article, we extract the plain text with anchors via WikiExtractor (Attardi, 2015) and then preprocess it with NLTK (Bird et al., 2009) for sentence segmentation and tokenization. We only consider the home articles of entities that appear as anchors in at least 10 other articles to construct the query. Then, for each anchor entity, we pair its query from home article with 10 relevant contexts from other reference articles that explicitly mention the corresponding anchors and construct positive MRC examples as described in Sec. 2. Negative examples are formed by pairing the query with 10 irrelevant contexts. In summary, the obtained pre-training corpus consists of 18 million MRC examples (6.4 billion words). Note that we also try various advanced data selection strategies, such as relevance-driven and diversity-driven ones, to pair the query and context. However, no significant performance gain is observed, and the detailed comparison is provided in Appendix A.3.

3.2 Downstream Extraction Tasks

We evaluate two extraction tasks: EQA and NER. EQA: We evaluate the proposed PMR on MRQA benchmark (Fisch et al., 2019). For the few-shot setting, we use the few-shot MRQA datasets sampled by Ram et al. (2021) and follow Chada and Natarajan (2021) to pick the dev set having the same number of examples as the training set to select the best checkpoint. Note that Ram et al. (2021) additionally construct BioASQ and TbQA few-shot train/dev/test data from their original dev sets. We only follow these settings in the few-shot experiments (Table 1). For other full-resource experiments and analyses, we follow Fisch et al. (2019) in both in-domain and out-of-domain evaluation.

NER: We evaluate on four NER tasks, including two flat NER tasks: CoNLL (Tjong Kim Sang and De Meulder, 2003) and WNUT (Derczynski et al., 2017) as well as two nested NER tasks: ACE04 (Mitchell et al., 2005) and ACE05 (Walker et al., 2006). For the few-shot setting, we follow Lu et al. (2022) to construct 5 splits of K-shot datasets for the above four tasks, where we sample K={4,8,16,32,64} sentences for each category, and follow the same dev set construction way as EQA. For the full-resource setting, we report the test set F1 using the best-performing checkpoint on the dev set.

3.3 Baselines and Implementation Details

We compare with (1) Vanilla PLMs: RoBERTa (Liu et al., 2019) and SpanBERT (Joshi et al., 2020) with a randomly-initialized Extractor; (2) RBT-Post, a continually pretrained RoBERTa with the MLM objective using our constructed data; and (3) Models bridging the pretrain-finetune gaps, including Splinter (Ram et al., 2021), FewshotBART (Chada and Natarajan, 2021), EntLM (Ma et al., 2022), T5 (Raffel et al., 2020) and UIE (Lu et al., 2022).

We apply PMR on RoBERTa because of its superior downstream performance. The Extractor is randomly initialized, introducing additional 1.6M parameters. Regarding the pre-training efficiency of PMR, with 4 A100 GPUs, it only takes 36 and 89 hours to complete 3-epoch training for base-sized and large-sized models, respectively. The hyperparameter settings for pre-training and fine-tuning can be found in Appendix A.2.

4 Main Results

Few-Shot Results The few-shot EQA and NER results are presented in Table 1 and Table 2. Overall, the poor few-shot capability of PLMs suggests that fine-tuning an MRC extractor from scratch with limited data is very challenging. Our PMR achieves significantly better results on all few-shot levels of the two tasks compared to the baseline RoBERTa, where it obtains an average improvement of 36.6 and 18.6 F1 on 64-shot EQA and 4-shot NER respectively. PMR is much more effective than RBT-Post, clearly showing the benefits of a seamless connection between the MRC-style pre-training and the MRC fine-tuning. Other models bridging the pretrain-finetune gaps also perform much better than fine-tuning existing PLMs, which is consistent with us. On EQA, though Fewshot-BART may benefit from a larger output space of generative model, resulting in better transferability in an extremely low-resource EQA setting (i.e. 16 shot), processing such large output is far more complicated than the discriminative MRC and is easier to overfit. Consequently, the MRC-based PMR is more effective in learning extraction capability

3https://dumps.wikimedia.org/enwiki/latest
from more training examples than FewshotBART, leading to better performance when there are more than 32 examples on EQA. Among NER models, UIE performs poorly on nested NER and, unfortunately, it mainly emphasizes on the structured prediction and is not applicable for more complicated extraction tasks, i.e. EQA. EntLM, as a prompt-based method following the MLM paradigm, is also not applicable to EQA. Moreover, with the help of MRC-style pre-training, our PMR can even work reasonably well as a zero-shot learner, as shown in Figure 3.

**Full-Resource Results** Table 3 shows the full-resource comparison results on EQA and NER. Despite the fact that more fine-tuning data could alleviate the pretrain-finetune discrepancy to some extent, our MRC-style pre-trained data is more abundant and diverse than the labeled data, which makes the model learn the extraction capability more effectively and allows more entities to fuse the semantics from their definitions. Therefore, we still observe that PMR can significantly and consistently outperform previous approaches, where PMRbase achieves 1.9 and 1.4 F1 improvements in average over RoBERTa on EQA and NER respectively. We also explore the limits of PMR on an even larger PLM, i.e. ALBERT\textsubscript{xxlarge} (Lan et al., 2020), on Appendix A.4.

### 5 Further Discussions

**Multi-Dataset Learning** With a unified paradigm, one straightforward extension is to fine-tune one PMR model for solving multiple downstream tasks. Here we consider multi-dataset learning
Table 2: NER performance (F1) in 5 few-shot settings. EntLM is not applicable for nested NER tasks.

(MLD): fine-tuning with multiple datasets from the same task type. We consider MLD on both few-shot and full-resource settings. To balance the ratio of different datasets in full-resource MLD, we follow Fisch et al. (2019) to sample 75k training examples for each EQA dataset, and perform an up-sampling (2 times) for WNUT. The results are presented in Table 4. Being able to share knowledge among multiple datasets, the MLD extension alleviates the data scarcity issue and thus significantly improves the few-shot performance over single-task PMR\textsubscript{large}. Meanwhile, in the full-resource setting, the MLD extension can also achieve a comparable performance while greatly saving parameters. One exception is WNUT because it is constructed from social media text, significantly different from the exceptions in the news or Wikipedia sentences of the others. We also conducted multi-task learning (MTL) experiments, i.e. fine-tuning one model with combined datasets across different tasks. As expected, MTL results are weaker than the single task because these tasks may interfere with each other due to their different nature. But the reasonably small gaps still show the robustness of PMR. The results are detailed in Appendix A.5.

Out-of-Domain Generalization

Domain generalization is another common low-resource scenario, where the knowledge can be borrowed from the resource-rich domain to the resource-poor domain. We evaluate the domain generalization capability of the proposed PMR on MRQA benchmark, which provides meaningful out-of-domain (OOD) datasets mostly converted from other tasks (e.g. Multi-choice QA) and substantially different from SQuAD in terms of text domain. As shown in Table 5, our PMR significantly surpasses RoBERTa on all of 6 OOD datasets (+4.5 F1 on average), although they have similar in-domain performance on SQuAD, which verifies that our PMR with MRC-style pre-training can help capture QA patterns that are more generalizable to unseen domains. In addition, PMR also achieves a better generalization capability than T5-v1.1 with less than half parameters.

6 Explainable Sequence Classification

As mentioned in Sec. 2.2, sequence classification can also be viewed as an extraction task in our

Table 3: Full-resource results on EQA and NER. For EQA, we report the average F1 score on six MRQA in-domain dev sets. For NER, we report the average F1 score from the above 4 datasets. The detailed results of each individual dataset can be found in Table 11. \(\Delta\) indicates that T5-v1.1 only bridges the learning objective gap but not data format gap.

The Broncos took an early lead in Super Bowl 50 and never trailed. Newton was limited by Denver’s defense, which sacked him seven times and forced him into three turnovers, including a fumble which they recovered for a touchdown. Denver linebacker Von Miller was named Super Bowl MVP, recording five solo tackles. 2% sacks, and two forced fumbles.

1. How many solo tackles did Von Miller make at Super Bowl 507?

   \textbf{Gold: five solo tackles}  \textbf{PMR: five solo tackles}

2. Which Newton turnover resulted in seven points for Denver?

   \textbf{Gold: a fumble}  \textbf{PMR: two forced fumbles}

Figure 3: Zero-shot learning example of PMR\textsubscript{large} on SQuAD. For more details, refer to Appendix A.5.

Table 4: Out-of-domain generalization results on SQuAD. We report the average F1 score on six MRQA in-domain dev sets. For NER, we report the average F1 score from the above 4 datasets. The detailed results of each individual dataset can be found in Table 11. \(\Delta\) indicates that T5-v1.1 only bridges the learning objective gap but not data format gap.
MRC formulation. Therefore, we also try PMR on three Multi-Choice QA (MCQA) tasks: i.e., DREAM (Sun et al., 2019), RACE (Lai et al., 2017), and MCTest (Richardson et al., 2013), one natural language inference task: MNLI (Williams et al., 2018), as well as one sentiment analysis task: SST-2 (Socher et al., 2013) that cover most sequence classification types.

**Comparison Results** Table 6 shows the results of PMR and previous strong approaches on those tasks. Overall, PMR can maintain comparable performance as the strongest baseline, i.e. RoBERTa, and achieves better average results, indicating solving sequence classification in an MRC formulation is feasible and effective.

**Explainability** Moreover, recall that we restrict the extraction space to [CLS] token only, and use its extraction probability to determine which class label (query) the input text (context) belongs to. While we can still ask PMR to extract context tokens just as common extraction tasks, and it is interesting to investigate what PMR can extract from the context in absence of the fine-grained fine-tuning supervision. Therefore, we re-run the fine-tuned PMR\textsubscript{large} to additionally extract a span with the highest $S_{i,j}$ score from the context of SST-2, presented in Table 7. Surprisingly, the extracted spans are clear rationales supporting the sequence-level prediction (i.e., the overall sentiment of the input sentence). To verify this, we further conduct quantitative analysis by randomly checking 300 test instances and find about 74\% of the extracted spans are reasonable rationales for the sentiment prediction. These findings suggest that the fine-tuned PMR on SST-2 still largely preserves the conditional span extraction capability inherited from the MRC pre-training. Such capability allows the model to invoke semantic interactions for finding relevant context spans to the label-encoded query (e.g. “Negative. Feeling bad.”). Therefore, in addition to the performance improvement, PMR also offers high explainability for the classification results.

### 7 Related Work

**MRC** MRC was originally used to tackle natural language question tasks such as EQA and MCQA (Rajpurkar et al., 2016; Lai et al., 2017; Jiao et al., 2021). Then, recent efforts that represent task-specific labels as MRC queries have demonstrated the capacity to effectively address NLU tasks in the
MRC paradigm (Keskar et al., 2020; McCann et al., 2018). For example, Chai et al. (2020) formulate sequence classification tasks as MRC problems, where the model is instructed on informative label descriptions. Similarly, MRC enables the tokens to attend to the most salient text in the label description, leading to better performance for span extraction tasks, such as NER (Li et al., 2020), and event detection (Liu et al., 2020, 2021a). Moreover, MRC provides a unified model architecture for different NLU tasks and thus allows knowledge to transfer among domains or tasks. Therefore, NLU tasks like relation extraction (Li et al., 2019), aspect-based sentiment analysis (Mao et al., 2021) and coreference resolution (Wu et al., 2020), can be decomposed into multiple sequence classification and span extraction tasks and apply the same MRC model to achieve multi-task learning.

Hyperlinks for NLP Hyperlinks are exploited in two ways. First, hyperlinks are regarded as a kind of relevance indicator. In the context of model pre-training, Yasunaga et al. (2022) requires their model to predict the hyperlink relation in addition to the next-sentence relation of BERT. More widely, they are used in the Open-Domain QA (ODQA) in order to train a good retriever (Chang et al., 2020; Seonwoo et al., 2021). Some works further combine multiple hyperlinks into a knowledge graph to capture multi-hop relations between different Wikipedia articles for multi-hop QA (Asai et al., 2020; Yang et al., 2018). Our PMR differs from ODQA in that ODQA emphasizes the retrieval process given the fixed queries while the queries in PMR are also automatically constructed. Second, the anchors labeled by those hyperlinks can serve as entity annotation for representation learning. Many works apply MLM typically on those anchors to learn good entity representation to tackle knowledge-intensive tasks (Yamada et al., 2020; Calixto et al., 2021). As a result, PMR successfully combines the advantages of the two attempts, where our MRC query and context are paired in consideration of the relevance provided by hyperlinks and the anchors are automatically labeled as our MRC answers.

8 Conclusions

This paper presents a novel MRC-sytle pre-training model, namely PMR. PMR can fully resolve the learning objective and data format gaps that frequently appear in fine-tuning existing PLMs. Experimetal results over multiple dimensions, including effectiveness in solving few-shot tasks, out-of-domain generalization, demonstrate its strong benefits in bridge the pretrain-finetune gaps. PMR also shows encouraging potential in explaining the sequence classification process in an extraction-driven MRC framework.

A Appendix

A.1 Fine-tuning Tasks

For EQA, we use the MRQA benchmark (Fisch et al., 2019), including SQuAD (Rajpurkar et al., 2016), TriviaQA (Joshi et al., 2017), NaturalQuestions (Kwiatkowski et al., 2019), NewQA (Trischler et al., 2017), SearchQA (Dunn et al., 2017), HotpotQA (Yang et al., 2018), BioASQ (Tsatsaronis et al., 2015), DROP (Dua et al., 2019), DuoRC (Saha et al., 2018), RACE (Lai et al., 2017), RelationExtraction (Levy et al., 2017), TextbookQA (Kembhavi et al., 2017). EQA has always been treated as an MRC problem, where the question serves as the MRC query, and the passage containing the answers serves as the MRC context. For NER, We follow Li et al. (2020) to formulate NER into the MRC paradigm, where the entity label together with its description serves as the MRC query, and the input text serves as the MRC context. The goal is to extract the corresponding entities as answers. We use the Eq. 4 as the learning objective, where $Y_{ext}^{i,j}$ indicates that the input span $X_{i,j}$ is an answer/entity.

For sequence classification tasks, we construct the MRC query and context as followed. MCQA: The query is the concatenation of the question and one choice, and the context is the supporting document. MNLI: The query is the entailment label concatenated with the label description, and the context is the concatenation of the premise and hypothesis. SST-2: The query is the sentiment label concatenated with the label description, and the context is the input sentence. We use the Eq. 3 to fine-tune the classification tasks. Note that only the correct query-context pair would get $Y^{cls} = 1$. Otherwise, the supervision is $Y^{cls} = 0$. During inference, we select the query-context pair with the highest $S_{1,1}$ among all MRC examples constructed for the sequence classification instance as the final prediction.

A.2 Implementations

We use Huggingface’s implementations of RoBERTa (Wolf et al., 2020). During pre-training stage, the window size $W$ for choosing context sentences is set to 2 on both sides. We use the first $T = 1$ sentence as the MRC query. Sometimes, the sentence segmentation would wrongly segment a few words to form a sentence, which is not meaningful enough to serve as an MRC query. Therefore, we continue to include subsequent sentences to form the query as long the query length is short than 30 words. The learning rate is set to $1e-5$, and the training batch size is set to 24 and 40 for PMR$_{base}$ and PMR$_{large}$ respectively in order to maximize the usage of the GPU memory. We follow the default learning rate schedule and dropout settings used in RoBERTa. We use AdamW (Loshchilov and Hutter, 2019) as our optimizer. We train both PMR$_{base}$ and PMR$_{large}$ for 3 epochs on 4 A100 GPU. Since the WAE is a discriminative objective, the pre-training is extremely efficient, which tasks 36 and 89 hours to finish all training process for two model sizes respectively. We also reserve 1,000 home articles to build a dev set (20,000 examples) for selecting the best checkpoint. Since the queries constructed by these home articles have never been used in training, they can be used to estimate the general language understanding ability of the model instead of hand match.

During fine-tuning, the hyper-parameters for PMR$_{large}$ can be found in Table 8 and Table 10 for full-supervision and few-shot settings respectively.

A.3 Analysis of Data Construction

In addition to the defaulted way of constructing MRC examples (the first sentence in the home article is the query, and randomly find 10 contexts for pairing 10 MRC examples), we compare with some advanced strategies to pair the query and the context, including:

- Q-C Relevance: We still use the first sentence from home article as the query, but we only select the top $P\%$ or $P$ most similar contexts to the query, where the similarity score is computed as the combination of BM25 and SimCSE (Gao et al., 2021).
- Q Diversity: In searching for an anchor, we hope the query should be diverse enough such that the model would not make a hard match between the fixed query and the anchor. Therefore, we randomly select one sentence from the first $P$ sentences in the home article to serve as the query for the anchor, while we keep the same context selection strategy.
- C Diversity: We hope the contexts should also be diverse enough such that they provide more possible usages of an anchor. Therefore, We use K-means$^4$ to cluster all contexts contain-

We compare those advanced strategies with our defaulted one in Table 9, where two span extraction and sequence classification tasks are selected for evaluating the effectiveness of these strategies. First, we make a fast evaluation with only $L_{cls}$ without negative examples (i.e. Strategy 1,2,3). Comparing Q-C Relevance (top P%) against Q-C Relevance (top P), we can observe that it is better to sample contexts based on absolute values. In Wikipedia, the reference frequency of anchor entities are extremely unbalanced, where some frequent anchor entities such as "the United States" are referenced more 200,000 times, while other rare anchor entities are only mentioned once or twice in other articles. Therefore, Q-C Relevance (top P%) would waste too much focus on the well-learned frequent anchor entities and affect the learning of other less frequent anchor entities.

Then, when trained on both positive and negative examples as well well guided with both $L_{cls}$ and $L_{ext}$, we only sample absolute number of contexts. However, comparing among Strategy 4,5,6,7, no significant difference between these strategies and our random sampling is observed. We suggest that the benefits from these heuristic strategies are marginally in the presence of large-scale training data. Therefore, in consideration of the implementation simplicity, we just use the Random strategy as our final PMR implementation.

A.4 Fully-Resource Results

Table 11 compares PMR with strong approaches on full-resource setting. On EQA and NER, PMR can significantly and consistently outperform previous approaches, where PMR$_{large}$ achieves up to 3.7 and 2.6 F1 improvements over RoBERTa$_{large}$ on WNUT and SearchQA, respectively. For the base-sized models, the advantage of PMR is more obvious, i.e. 1.4 F1 over RoBERTa$_{base}$. Apart from those, we also observe that: (1) PMR can also exceed strong generative approaches (i.e. UIE, T5-v1.1) on most tasks, demonstrating that the MRC paradigm is more suitable to tackle NLU tasks. (2) RoBERTa-Post, which leverages our Wikipedia corpus (a subset of its original pre-training data) for MLM-style continued-pretraining, performs poorly on most tasks, especially those with natural-
solo tackles

Von Miller was named Super Bowl MVP, recording they recovered for a touchdown. Denver linebacker, which sacked him seven times and forced him into three turnovers, including a fumble which they recovered for a touchdown. Denver linebacker never trailed. Newton was limited by Denver's defense, which sacked him seven times and forced him into three turnovers, including

to some extent.

Table 11: Performance on EQA (F1), and NER (F1). The best models are bolded. For EQA, as done in Fisch et al. (2019), we report the F1 on dev set and produce the results of SpanBERT and LUKE following the same protocol. Although we try hard to produce the results of LUKE for TriviaQA and SearchQA, its performance is unreasonably low. For CoNLL, we assume there is no additional context available and therefore we retrieve the results of CL-KL w/o context from Wang et al. (2021). Results labeled by †, ‡, and † are cited from Wang et al. (2021); Yan et al. (2021); Lu et al. (2022), respectively.

question queries (i.e. EQA and MCQA). (3) PMR can be applied on even larger PLM such as ALBERTxlarge (Lan et al., 2020) to gain stronger representation capability and further improve the performance of downstream tasks. Such findings suggest that with our MRC data format and WAE objective, PMR can leverage the same data to learn a high level of language understanding ability, beyond language representation.

A.5 Zero-shot Learning

To reveal PMR's inherent capability from its MRC-style pretraining, we show its zero-shot performance in Figure 3, where the F1 and Exact Match (EM) scores on the entire SQuAD dev set and a case study in answering several questions are presented. Without any fine-tuning, our PMR achieves 10.4 EM, whereas T5 and RoBERTa can barely provide meaningful answer, as shown by their near zero EM scores. In the case study, our PMR correctly answers the first question. For the second question, although PMR gives an incorrect answer, the prediction is still a grammatical phrase. In contrast, RoBERTa and T5-v1.1 always perform random extractions and generations. Such a phenomenon verifies that PMR obtains a higher-level language digest capability from the MRC-style pretraining and can directly tackle downstream tasks to some extent.
A.6 Multi-task Learning

We present the results on multi-task learning (MTL): fine-tuning with datasets across all tasks setting. We combine the training sets of CoNLL from NER, SQuAD from EQA, and SST-2 from sequence classification for training the MTL model. The results of MTL extension on Table 12 suggest that, based on the proposed PMR, token-level and sequence-level NLU tasks can also be jointly trained at a cost of minor performance drop.
