Abstract

Deep networks for computer vision are not reliable when they encounter adversarial examples. In this paper, we introduce a framework that uses the dense intrinsic constraints in natural images to robustify inference. By introducing constraints at inference time, we can shift the burden of robustness from training to the inference algorithm, thereby allowing the model to adjust dynamically to each individual image’s unique and potentially novel characteristics at inference time. Among different constraints, we find that equivariance-based constraints are most effective, because they allow dense constraints in the feature space without overly constraining the representation at a fine-grained level. Our theoretical results validate the importance of having such dense constraints at inference time. Our empirical experiments show that restoring feature equivariance at inference time defends against worst-case adversarial perturbations. The method obtains improved adversarial robustness on four datasets (ImageNet, Cityscapes, PASCAL VOC, and MS-COCO) on image recognition, semantic segmentation, and instance segmentation tasks. Project page is available at equi4robust.cs.columbia.edu.

1. Introduction

Despite the strong performance of deep networks on computer vision benchmarks [23, 24, 48], state-of-the-art systems are not reliable when evaluated in open-world settings [5, 16, 21, 25, 26, 41]. However, the robustness against a large number of adversarial cases remains a prerequisite necessary to deploy models in real-world applications, such as in medical imaging, healthcare, and robotics.

Due to the importance of this problem, there has been a large number of investigations aiming to improve the training algorithm to establish reliability. For example, data augmentation [25, 49] and adversarial training [6, 32] improve robustness by training the model on anticipated distribution shifts and worst-case images. However, placing the burden of robustness on the training algorithm means that the model can only be robust to the corruptions that are anticipated ahead of time, which is an unrealistic assumption in an open world. In addition, retraining the model on new distributions each time can be expensive.

To address this challenge, we propose to robustify the model at inference time. Specifically, instead of retraining the whole model on the new distribution, our inference-time defense shifts the burden to test time with our robust inference algorithm without updating the model. Prior work [34, 39, 42] is limited to a single constraint at inference time and hence may not provide the model with enough information to dynamically adjust to the unique and potentially novel characteristics of the corruption in the testing image. We therefore ask the natural question: Can we further improve the robustness through increasing the number of constraints?

We start with theoretical analysis and prove that applying more constraints at inference time does strictly improve the model’s robustness. The next question is then: What is the best approach for applying multiple constraints at inference time? One approach is to directly apply multiple feature invariance constraints to the defense. While this defense is effective, we find the resulting representation can be limited by the invariance property, therefore harming robust accuracy. For example, after resizing, the representations of the segmentation models are not the same, and it is unclear
which part should be invariant.

Our further study with empirical results suggest that a better approach is to use dense equivariance constraints. Our main hypothesis is that visual representations must be equivariant under spatial transformations, which is a dense property that should hold for all natural images. We show an example of equivariance consistency in Figure 1. This property holds when the test data are from the same distribution that the model has been trained on. However, once there has been an adversarial corruption, the equivariance is often broken (Figure 2). Therefore our key insight is that we can repair the model’s prediction on corrupted data by restoring the equivariance.

Empirical experiments, theoretical analysis, and visualizations highlight that equivariance significantly improves model robustness over other methods [34, 39, 42]. On four large datasets (ImageNet [17], Cityscapes [14], PASCAL-VOC [20], and MS-COCO [31]), our approach improves adversarial robust accuracy by up to 15 points. Even under two adaptive adversarial attacks where the attacker knows our defense [3, 34], adding our method improves robustness. In addition, since equivariance is an intrinsic property of visual models, we do not need to train a separate model to predict equivariance [34, 39]. We will release the model and code.

2. Related Work

Equivariance. Equivariance benefits a number of visual tasks [13, 18, 22]. [12] proposed the first group-convolutional operation that produces equivariant features to symmetry-group. However, it can only be equivariant on a discrete subset of transformation [40]. Steerable equivariance achieves continuous equivariant transformation [13, 45] on the defined set of basis, but they cannot be applied to arbitrary convolution filters due to the requirement of an equivariant basis. Besides architecture design [44], adding regularization [4] can improve equivariance in the network. [27] shows that training equivariance at training time decreases adversarial robustness. Our hypothesis is that the model is burdened at training time with both equivariance and the task of interest, where we instead propose to overcome this by fixing equivariance at inference time.

Adversarial Attack and Defense. Adversarial attacks [2, 5, 10, 16, 19, 32, 41] are perturbations optimized to change the prediction of deep networks. Adversarial training [6, 32, 38] and its variants [36, 51] are the standard way to defend adversarial examples. The matching algorithm to produce features invariant to adversarial perturbations has been shown to produce robust models [33, 51]. However, training time defense can only be robust to the attack that it has been trained on. Multitask learning [35, 50] and regularization [11] can improve adversarial robustness. However, they did not consider the spatial equivariance in their task. Recently, inference time defense using contrastive invariance [34] and rotation [39] has been shown to improve adversarial robustness without retraining the model on unforeseen attacks. However, they only apply a single constraint, which may not provide enough information.

3. Method

In this section, we first introduce equivariance for visual representation, present algorithms to improve adversarial robustness using equivariance, and then provide theoretical insight into why the multiple constraints can lead to such improvement.

3.1. Equivariance in Vision Representation

Let \( x \) be an input image. A neural network produces a representation \( h = F_\theta(x) \) for the input image. Assume there is a transformation \( g \) for the input image. A neural network is equivariant only when:

\[
F_\theta(x) = g^{-1} \circ F_\theta \circ g(x),
\]

where \( g^{-1}(\cdot) \) denotes the inverse transformation for \( g(\cdot) \), and \( \circ \) denotes function composition. Equivariant representations will change symmetrically as the input transformation. This means applying the transformation to the input image and undoing the transformation in the representation space, should result in the same representation as fed in the original image. Equivariance provides a meta property that can be applied to dense feature maps, and generalized to most existing vision tasks [22, 29, 37].

In contrast, invariance is defined as \( F_\theta(x) = F_\theta \circ g(x) \), which requires the model to produce the same representation after different transformations, such as texture augmentation [21] and color jittering [9, 34]. Without performing transformation in the same way as the input, invariance removes all the information related to the transformation, which can hurt the final task if the transformation is crucial to the final task [30]. On the contrary, equivariant models maintain the covariance of the transformations [22, 29, 37] in feature space.

Transformation for Equivariance. We use spatial transformation, such as flip, resizing, and rotation, in our experiments. Assume we apply \( k \) different transformations \( g_i \) where \( i = 1, ..., k \). We denote the cosine similarity as \( \cos(\cdot) \). Equivariance across all transformations means the following term is large:

\[
L_{\text{equiv}} = \sum_{i=1}^{k} \cos(g_i^{-1} \circ F_\theta \circ g_i(x), F_\theta(x))
\]
Algorithm 1 Equivariance Defense

1: **Input:** Potentially attacked image $x$, step size $\eta$, number of iterations $T$, deep network $F$, reverse attack bound $\epsilon_v$, and equivariance loss function $\mathcal{L}_{equi}$.
2: **Output:** Prediction $\tilde{y}$
3: **Inference:** $x' \leftarrow x$
4: for $t = 1, ..., T$ do
5: $x' \leftarrow x' + \eta \cdot \text{sign} (\text{Normalize}(\nabla_x \mathcal{L}_{equi}(x')) + \mathcal{N}(0, \frac{T-t}{T}))$
6: $x' \leftarrow \Pi(x, \epsilon_v)x'$, which projects the image back into the bounded region.
7: end for
8: Predict the final output by $\tilde{y} = F(x')$

3.2. Equivariance for Adversarial Robustness

Let $y$ be the ground-truth category labels for $x$. Let the network that uses the feature $h$ for final task prediction to be $C_{\theta'}$. For prediction, neural networks learn to predict the category $\tilde{y} = C_{\theta'} \circ F_{\theta}(x)$ by minimizing the loss $L(\tilde{y}, y)$ between the predictions and the ground truth. For example, for semantic segmentation, $L$ is cross-entropy for each pixel output. We define the loss for the final task as follows:

$$L_t(x, y) = L(C_{\theta'} \circ F_{\theta}(x), y),$$

Adversarial Attack. To fool the model’s prediction, the adversarial attack finds additive perturbations $\delta$ to the image such that the loss of the task (Equation 3) is maximized.

$$x_a = \arg \max_{x_a} \mathcal{L}_t(x_a, y), \quad \text{s.t.} \quad ||x_a - x||_q \leq \epsilon_v,$$

where the perturbation vector $\delta = x_a - x$ has a $q$ norm bound that is smaller than $\epsilon_v$, keeping the perturbation invisible to humans.

Equivariance Recalibration Defense. Given an input image, we can calculate the equivariant loss $\mathcal{L}_{equi}$. As shown in Figure 2, the representations are non-equivariant when the input $x_a$ is adversarially perturbed, i.e., the term $\mathcal{L}_{equi}$ is low. We will find an intervention to recalibrate the input image $x_a$ such that we can improve the feature equivariance of the image. To do this, we optimize a vector $r$ by maximizing the equivariance objective:

$$r = \arg \max_r \mathcal{L}_{equi}(x_a + r), \quad \text{s.t.} \quad ||r||_q \leq \epsilon_v,$$

where $\epsilon_v$ defines the bound of our reverse attack $r$. The additive intervention $r$ will modify the adversarial image $x_a$ such that it restores the equivariance in feature space.

We optimize the above objective via projected gradient descent to repair the input. To avoid the optimization converging to a local optimal, we first perform SGLD [46]
to get a good Bayesian posterior distribution of the solution \[43\]. To avoid sampling from the posterior distribution of SGLD and improve the inference speed, we then use maximum a posteriori (MAP) estimation to find a single solution. Empirically, we add Gaussian noise to the gradient when optimizing and linearly anneal the noise level to zero. We show the optimization procedure in Algorithm 1. We use the same optimizer for the invariance objective and compare.

One advantage of our approach over \[34, 39\] is that we do not need to pre-train another network for the self-supervision task offline. In addition, equivariance in the feature space provides a dense constraint because, by projecting the transformation back to the original space, we can match each element in the feature space. Image-level self-supervision tasks, such as contrastive loss and rotation prediction, do not have this dense supervision advantage.

**Adaptive Attack I.** We now analyze our methods’ robustness when the attacker knows our defense strategy and takes our defense into consideration. Following the defense-aware attack setup in \[34\], the adaptive attacker can maximize the following equation:

\[
\mathcal{L}_1(x_a, y, \lambda_s) = \mathcal{L}_t(x_a, y) + \lambda_s \mathcal{L}_{eq1}(x_a).
\]

where the first term fools the final task, and the second term optimizes for equivariance. A larger \(\lambda_s\) allows the adversarial budget to focus more on respecting the feature equivariance, which reduces the defense capability of our defense. However, with a fixed adversarial budget, increasing \(\lambda_s\) also reduces the attack efficiency for the final task. Our defense creates a lose-lose situation for the attacker. If they consider our defense, they hurt the attack efficiency for the final task. If they ignore our defense, our defense will fix the attack.

**Adaptive Attack II.** The above adaptive attack avoids the unstable gradient from the iterative optimization with a Lagrangian regularization term. Another way to bypass such defense is through BPDA \[3\]. Specifically, the equivariance recalibration process formulated in Eq. 5 can be treated as a preprocessor \(h(\cdot)\) that is employed at test time, where \(h(x_a) = x_a + r\). Given a pre-trained classifier \(f(\cdot)\), this method can be formulated as \(f(h(x))\). The proposed process \(h(\cdot)\) may cause exploding or vanishing gradients. According to \[3, 15\], we can use BPDA to approximate \(h(\cdot)\), where an identity function is used for the backward pass of the restored images. While this method may make the backward gradient inaccurate, it avoids differentiation through the inner optimization procedure, which often leads to vanished or exploded gradients.

### 3.3. Theoretical Results for Adversarial Robustness with Multiple Constraints

One major advantage of equivariance is that it allows dense constraints through the inverse transformation. We show theoretical insights for why using a dense intrinsic constraint rather than a single intrinsic constraint. Existing methods restore the input image to respect a single self-supervision label \(y^{(s_1)}\). With a dense intrinsic constraint, the defense model can predict with a set of fine-grained self-supervision signals, \(y^{(s_i)}\), where \(i = 1, 2, ..., K\). In our case, each \(y^{(s_i)}\) is the predicted self-supervision value under adversarial attack, and each \(y^{(s_i)}\) is the predicted self-supervision value in our feature vector after equivariance transformation. Following \[34\], we propose the following lemma:

**Lemma 3.1.** The standard classifier under adversarial attack is equivalent to predicting with \(P(Y|X_a, y^{(s_1)}, y^{(s_2)}, ..., y^{(s_K)})\), and our approach is equivalent to predicting with \(P(Y|X_a, y^{(s_1)}, y^{(s_2)}, ..., y^{(s_K)})\).

By adjusting the input image such that it satisfies a set of denser constraints, the predicted task \(Y\) uses both the information from the image and the intrinsic equivariance structure. We now show that by restoring the dense constraints in our visual representation, from an information perspective, the upper bound can be strictly improved than just restoring the structure from a single self-supervision task \[34, 39\].

**Theorem 3.1.** Assume the classifier operates better than chance and instances in the dataset are uniformly distributed over \(n\) categories. Let the prediction accuracy bounds be \(P(Y|y^{(s_1)}, y^{(s_2)}, ..., y^{(s_K)}, X_a) \in [b_0, c_0]\), \(P(Y|y^{(s_1)}, X_a) \in [b_1, c_1]\), \(P(Y|y^{(s_2)}, X_a) \in [b_2, c_2]\), ..., and \(P(Y|y^{(s_K)}, y^{(s_{K-1})}, ..., y^{(s_1)}, X_a) \in [b_K, c_K]\). If the conditional mutual information \(I(Y; Y^{(s_i)}|X_a) > 0\) and \(I(Y; Y^{(s_i)})|X_a, Y^{(s_j)}) > 0\) where \(i \neq j\), we have \(b_0 \leq b_1 \leq ... \leq b_k\) and \(c_0 < c_1 < c_2 ... < c_k\), which means our approach strictly improves the upper bound for classification accuracy.

In words, the adversarial perturbation \(X_a\) corrupts the shared information between the label \(Y\) (our target task) and the equivariance structure \(Y^{(s_i)}\) (self-supervised task). Theorem 3.1 shows that by recovering information from
more $Y^{i*}$, the task performance can be improved. Our empirical result in Figure 3 also validates the trend of improving robustness as the number of constraints increases.

The adaptive attack needs to respect the information in $Y^{i*}$, which itself limits the ability of the attacker, as the attacker performs a multitask optimization which is harder [35]. In addition, the adaptive attacker predicts the task conditioned on the right set of self-supervision label $Y^{i*}$, which fulfills our Theorem 3.1 and improves the bound for robustness.

4. Experiments

Our experiments evaluate the adversarial robustness on four datasets: ImageNet [17], Cityscapes [14], PASCAL-VOC [20], and MS-COCO [31]. We use up to 6 different strong attacks, including Houdini, adaptive attack, and BPDA to evaluate the robustness. We first show that our equivariance-based defense improves the robustness of the state-of-the-art adversarially trained robust models. We then show that even on the standard models without defense training, adding test-time equivariance can improve their robustness.

4.1. Dataset and Tasks

*ImageNet* [17] contains 1000 categories. Due to its large size, we sample 5% of data for evaluation. *Cityscapes* [14] is an urban driving scene dataset. We study the semantic segmentation task. Following [35], we resize the image to $680 \times 340$ for fast inference. We use pretrained dilated residual network (DRN) for segmentation. *PASCAL-VOC* [20] is a dataset for semantic segmentation task. We resize images to $480 \times 480$. We use the pre-trained DeepLabV3+ model. *MS-COCO* [31] is a large-scale image dataset of common objects that supports semantic segmentation and instance segmentation task. For semantic segmentation, we resize the images to $400 \times 400$. We use pretrained DeeplabV3 and MaskRCNN for semantic segmentation and instance segmentation, respectively.

4.2. Attack Methods

*IFGSM* [2] was used to evaluate the robustness of segmentation models with multiple steps of the fast gradient sign method. *PGD* [32] is a standard iterative-based adversarial attack, which performs gradient ascent and projects the attack vector inside the defined $p$ norm ball. *MIM* [19] adds a momentum term to the gradient ascent of PGD attack, which is a stronger attack that can get out of local optima. *Houdini* [10] is the state-of-the-art adversarial attack for decreasing the mIoU score of semantic segmentation. It proposes a surrogate objective function that can be optimized on the mIoU score directly. *Adaptive Attack (AA)* [34] is the standard defense-aware attack for inference time defense method, where the adaptive attack knows our defense algorithm, and optimizes the attack vector to respect equivariance while fooling the final task. Since the attack already respects and adapts to equivariance, our defense has less space to improve by further optimizing for equivariance. *BPDA* [3,15] is an adaptive attack for input purification. In our case, we forward the adapted images in the forward pass and straight-through the gradient from our adapted image to the input image.

4.3. Baselines

We compare our method with the vanilla feed-forward inference and four existing inference-time defense methods. *Random* defense [28] defends adversarial attack by adding random noise to the input, which is used as a baseline in [34]. *Rotation* defense [39] purifies the adversarial examples by restoring the performance of the rotation task at inference time, which can recover the image information that relates to rotation. However, the information related to rotation may be misleading due to the illusion issue [1], which limits its power for complex tasks. *Contrastive defense* [34] restores the intrinsic structure of the image using SimCLR [9] objective at inference time, which achieves state-of-the-art adversarial robustness on image recognition tasks. Contrastive learning requires images to be object-centric, which may not be true on the segmentation and detection dataset where multiple objects appear in the same image. *Invariance* defense follows the same setup as our equivariance experiment but replaces the equivariance loss with the invariance loss. The setup is the same as our equivariance, but the only difference is that we use the invariance loss function. It is also proposed by us and aims to compare with the equivariance objective.

4.4. Implementation details

We choose the number of transformations to be $K = 8$, which empirically can be fit into a 2080Ti GPU with batch size 1. Among the transformations, we use four resizing transformations ranging from 0.3 to 2 times of size change; one color jittering transformation; one horizontal flip transformation; and two rotation transformations between -15 to 15 degrees. We use steps $T = 20$ for all our defense tasks. Since after the spatial transformations, the invariance objective cannot be performed in the dense feature space due to the position mismatch, we apply an average pooling for all the features and then compute the invariance loss.

4.5. Results on Adversarial Trained Models

Adversarial training is the standard way to defend against adversarial examples. We first validate whether our proposed approach can further improve the robustness of adversarially trained models. For ImageNet, we use the adversarial pretrained model with $\epsilon = 4/255$ from [47]. We set the defense vector bound to be $\epsilon_v = 2\epsilon$. With the
state-of-the-art contrastive learning method [34], we improve robustness accuracy by 3 points to the Vanilla defended model. Adaptive attack (AA) poses a lose-lose situation and does not further decrease the robustness accuracy, which is consistent with the observation of [34]. With the strongest adaptive attack BPDA [15], it drops 0.5 points. Using the equivariance objective, under both standard attack and the adaptive attack BPDA, it improves robustness more than the other methods. Even though BPDA decreases equivariance defense by 1.8 points, equivariance still improves robustness by 3.9 points than not using it.

On Cityscapes, we downsample the image from $2048 \times 1024$ to $680 \times 340$ to reduce computation, which follows the setup of [35]. We adversarially train a segmentation model and evaluate it in Table 1, which is measured with mean Intersection over Union (mIoU) for semantic segmentation. We set the defense vector bound to be $\epsilon_v = 2.5 \epsilon$. For the standard attack, Houdini reduces the robustness accuracy the most, where using equivariance constraints at test time can recover 6 points of performance. Using the adaptive attack [34], the robust accuracy of equivariance only drops by 0.2 points. Using the BPDA adaptive attack, the robustness of the invariance-based method drops 4 points, which suggests that invariance relies mostly on obfuscated gradients and it is not an effective constraint to maintain at inference time for segmentation. In contrast, BPDA cannot undermine the equivariance-based model’s robustness. On the adversarially trained model, equivariance consistently outperforms all other test-time defenses, which demonstrates that equivariance is a better intrinsic structure to respect during inference time.

### 4.6. Results on Non-Adversarial Trained Models

We have shown that equivariance improves the robustness of adversarially trained models. However, most pretrained models are not adversarially defended. We thus study whether our method can also improve standard models’ robustness.

**CityScapes Semantic Segmentation.** In Table 2, we first conduct five types of attacks for the DRN-22-d segmentation model. We use 20 steps of defense, i.e., $K = 20$, and use a step size of $\eta = 2 \epsilon_v$, and set the defense vector bound to be $\epsilon_v = 1.5 \epsilon$. While the strongest Houdini attack can reduce the mIoU score to 0, our defense can restore the mIoU score by over 30 points. For the adaptive attack, we search the optimal $\lambda_e$ that reduces the robust performance the most and find $\lambda_e = 1000$ produces the most effective attack, which still cannot bypass our defense. Since our method achieves significantly higher robust performance than other methods, we do not evaluate adaptive attack for other defenses, as it will further decrease the robustness of other defenses. We find for standard backbones that are not adversarially trained, BPDA is the most effective attack. We run 50 steps of BPDA. Under the BPDA attack, equivariance-based defense is still more effective than other methods, including the invariance-based method.

**PASCAL VOC Semantic Segmentation.** We show results in Table 2. We use the pretrained DeepLabV3 [7, 8] model.
Table 2. Semantic segmentation mIoU on Cityscapes, PASCAL VOC, and MSCOCO dataset. All models are not adversarially trained. Under different types of attack bounded by $L_\infty = 4/255$, our method consistently outperforms other defense methods.

Table 6. Trading-off Robustness vs. Clean Accuracy on Cityscape using our equivariance method under BPDA attack. If clean performance is important, we can simply decrease the defense vector bound to increase the clean accuracy.

Applied to a large number of vision applications.

Targeted Attack. The above attacks are untargeted. We also analyze whether our conclusion holds under targeted attacks, where the attacker needs to fool the model to predict a specific target. In Table 3, the targeted attack successfully misleads the model to predict the target, and our equivariance defense corrects the prediction to be the ground truth. Equivariance improves up to 10 points on the mIoU metric. We show visualizations in Figure 4.

4.7. Analysis

Equivariance Measurement. We calculate the equivariance value measured by Equation 2 for clean images, adversarial attacked images, and our defended images. We show the numerical results in Table 4. While adversarial attacks corrupt the equivariance of the image, as shown by the lowered value in the table, our method is able to restore it. Visualizations in Figure 2 also show our method clearly restores the equivariance under attack.

Ablation Study for Equivariance Transformations. In Table 5, we study the impact of using different transformations in our equivariance defense. We find transformations, which the model should be equivariant to but, in fact, does not due to attacks, are the most effective ones in improving robustness. For example, flipping and resizing are most effective for our studied semantic segmentation. Rotation below 15 degrees helps robustness more than rotation larger than 90 degrees. Large rotation performs worse because segmentation models are not equivariant to large rotation, even on clean data, which reduces the effectiveness of our approach. In Section 4.4, we empirically choose the combination of transformations that produces good empirical results for our approach.

The Trade-off between Robustness and Clean Accuracy. In Table 6, we show that increasing the bound $\epsilon_v$ for the defense vector creates a trade-off between clean accuracy and robust accuracy. Specifically, bound $\epsilon_v = 1/255$ is a sweet spot, where one can increase robustness by 0.4 without any loss of clean accuracy. Our method allows dynamically conducting trade-off between robustness and clean accuracy by controlling the additive vector’s bound.

5. Conclusion

Robust perception under adversarial attacks has been an open challenge. We find that equivariance can be a desired structure to maintain at inference time because it can provide dense structural constraints on a fine-grained level. By dynamically restoring equivariance at inference, we show significant improvement in adversarial robustness across three datasets. Our work hints toward a new direction that uses the right structural information at inference time to improve robustness.
