Mean Field Multi-Agent Reinforcement Learning

Yaodong Yang* 1 Rui Luo* 1 Minne Li1 Ming Zhou2 Weinan Zhang2 Jun Wang1

Abstract

Existing multi-agent reinforcement learning methods are limited typically to a small number of agents. When the agent number increases largely, the learning becomes intractable due to the curse of the dimensionality and the exponential growth of user interactions. In this paper, we present Mean Field Reinforcement Learning where the interactions within the population of agents are approximated by those between a single agent and the average effect from the overall population or neighboring agents; the interplay between the two entities is mutually reinforced: the learning of the individual agent’s optimal policy depends on the dynamics of the population, while the dynamics of the population change according to the collective patterns of the individual policies. We develop practical mean field Q-learning and mean field Actor-Critic algorithms and analyze the convergence of the solution. Experiments on resource allocation, Ising model estimation, and battle game tasks verify the learning effectiveness of our mean field approaches in handling many-agent interactions in population.

1. Introduction

Multi-agent reinforcement learning (MARL) is concerned with a set of autonomous agents that share a common environment (Busoniu & De Schutter). Learning in MARL is fundamentally difficult since agents not only interact with the environment but also with each other. Independent Q-learning (Tan, 1993) that considers other agents as a part of the environment quite often fails as the multi-agent environment breaks the theoretical convergence guarantees and makes the learning unstable: the changes in strategy of one agent would affect the strategies of other agents and vice versa (Matignon et al., 2012).

Instead, accounting for the extra information from conjecturing the policies of other agents would be beneficial to each single learner (Foerster et al., 2017; Lowe et al., 2017a). Studies have shown that an agent who learns the effect of joint actions has better performance than those who does not, in a number of scenarios including cooperative games (Panait & Luke, 2005), zero-sum stochastic games (Littman, 1994), and general-sum stochastic games (Littman, 2001; Hu & Wellman, 2003).

The existing equilibrium based approaches, although principled, are only capable of solving a handful of agents (Hu & Wellman, 2003; Bowling & Veloso, 2002). The computational complexity of directly solving (Nash) equilibrium would prevent them from applying for the situations there are a large body of agents or even a population of agents. Yet, in practice, many cases do require strategic interactions among a large number of agents, ranging from gaming bots in MMORPG (Massively Multiplayer Online Role-Playing Game) (Jeong et al., 2015) to trading agents in stock markets (Troy, 1997), and to online advertising bidding (Wang et al., 2017).

In this paper, we tackle MARL when a large number of agents co-exist. We consider a setting where each agent is directly interacting with a finite set of other agents; through a chain of direct interactions, any pair of agents is interconnected globally (Blume, 1993). The scalability is solved by employing Mean Field Theory (Stanley, 1971): the interactions within the population of agents are approximated by that of a single agent played with the average effect from the overall (local) population (Lasry & Lions, 2007). The learning is mutually reinforced between two entities rather than among many entities: the learning of the individual agent’s optimal policy is based on the dynamics of the agent population, while at the same time, the dynamics of the population is updated according to the individual policies. Based on the formulation, we develop practical mean field Q-learning and mean field Actor-Critic algorithms, and discuss the convergence of our solution under certain assumptions. Our experiment on a simple multi-agent resource allocation shows that our mean field MARL is capable of learning over many-agent interactions when others fail. We also demonstrate that with temporal-difference learning, mean field MARL manages to learn and solve an Ising model without even explicitly knowing the energy function. At last, in a mixed cooperative-competitive battle game, we show that the mean field MARL achieves high winning rates against other baselines previously reported for many agent systems.
2. Preliminary

MARL intersects between reinforcement learning and game theory. The marriage of the two gives rise to the general framework of Stochastic Game (van der Wal, 1980).

2.1. Stochastic Game

An N-agent (or, player) stochastic game \( \Gamma \) is expressed by a tuple \((\mathcal{S}, \mathcal{A}_1, \ldots, \mathcal{A}_N, r, p, \gamma)\), where \( \mathcal{S} \) denotes the state space and \( \mathcal{A}_j \) is the action space of agent \( j \) \((j = 1, \ldots, N)\). At each time step, all agents choose action simultaneously, which leads to their rewards. \( r : \mathcal{S} \times \mathcal{A}_1 \times \cdots \times \mathcal{A}_N \rightarrow \mathbb{R} \) is the reward function for agent \( j \). \( \gamma \) denotes the reward discount factor across the time.

The policy (or, strategy) for agent \( j \) is \( \pi_j : \mathcal{S} \rightarrow \Omega(\mathcal{A}_j) \) where \( \Omega(\mathcal{A}_j) \) is the collection of probability distribution over agent \( j \)'s action space \( \mathcal{A}_j \). \( \pi = \{\pi_1, \ldots, \pi_N\} \) denotes the joint policy of all \( N \) agents. \( \pi \) is usually assumed independent of time, also called stationary strategy. Given initial state \( s \) and certain policy \( \pi \), agent \( j \) aims to maximize the value function, namely:

\[
v^\pi_j(s) = v^\pi(s; \pi) = \sum_{t=0}^{\infty} \gamma^t \mathbb{E}_{\pi, \rho}\left[r_t | s_0 = s, \pi\right].
\]

We can define the \( Q \)-function in the framework of \( N \)-agent game based on the value function. The Bellman equation for \( Q \)-function of agent \( j \) under the joint policy \( \pi \) is \( Q^\pi : \mathcal{S} \times \mathcal{A}_1 \times \cdots \times \mathcal{A}_N \rightarrow \mathbb{R} \) such that

\[
Q^\pi_j(s, a) = r(s, a) + \gamma \mathbb{E}_{a' \sim \pi}\left[v^\pi_{j'}(s')\right].
\]

And the corresponding value function \( v^\pi_j \) for agent \( j \) under the joint policy \( \pi \) can be expressed in terms of \( Q \)-function

\[
v^\pi_j(s) = \mathbb{E}_{a \sim \pi}\left[Q^\pi_j(s, a)\right].
\]

Note that the \( Q \)-function for \( N \)-agent game extends the conventional formulation for single-agent game by including actions taken by all \( N \) agents \( a = \{a_1, \ldots, a_N\} \), and by taking the expectation over the actions of all agents.

We model the MARL problem by the stochastic game in a discrete-time and non-cooperative setting (no explicit coalitions are considered). We assume the game has incomplete but perfect information (Littman, 1994), i.e., agents do not know the game dynamics or the reward functions of others, but they can observe other agents’ immediate reward and actions taken previously.

2.2. Nash \( Q \)-learning

In MARL, the goal is to learn an optimal strategy for each agent. In stochastic games, the notion of Nash equilibrium is thus of great importance (Hu & Wellman, 2003); it is represented as a set of \( N \) policies \( \pi_1^* = \{\pi_1^*, \ldots, \pi_N^*\} \) such that \( \forall \pi' \in \Omega(\mathcal{A}_j), \) it satisfies

\[
v^\pi_j(s; \pi_1^*) = v^\pi_j(s; \pi_1^*, \pi_2, \ldots, \pi_N^*) \geq v^\pi_j(s; \pi_1^*, \pi_2, \ldots, \pi_j, \pi_j', \ldots, \pi_N^*)
\]

where we adopt compact notations for the joint policy of all agents except \( j \) as \( \pi_j' \) to others, provided that all other agents follow the policy \( \pi_j^* \). It has been shown, for every \( N \)-agent stochastic game, there is at least one Nash equilibrium in stationary strategies (Fink et al., 1964). Given a set of Nash strategy \( \pi_j^* \), the Nash value function \( v^{\text{Nash}}(s) = (v^{\text{Nash}}_1(s), \ldots, v^{\text{Nash}}_N(s)) \) stands as the expected sum of discounted rewards if all agents follow these Nash policies from state \( s \) onward.

Nash \( Q \)-learning (Hu & Wellman, 2003) is an iterative procedure of calculating the Nash policy: 1) solving a Nash equilibrium through the Lemke-Howson algorithm (Lemke & Howson, 1964) for the current stage game \( \{Q'_t\} \), 2) improving the estimation of the Nash \( Q \)-function using the new Nash policy. Nash \( Q \) keeps iterating the above two steps until the \( Q \)-value converges. It is shown that under certain assumptions, the Nash \( Q \) operator \( \mathcal{H}_t^{\text{Nash}}Q = (\mathcal{H}_t^{\text{Nash}}Q_1, \ldots, \mathcal{H}_t^{\text{Nash}}Q_N) \) defined as

\[
(\mathcal{H}_t^{\text{Nash}}Q)(s, a) \equiv \mathbb{E}_{s' \sim p}\left[r(s, a) + \gamma v^{\text{Nash}}_j(s')\right]
\]

is a contraction mapping given that \( \pi \) is an appropriate Nash equilibrium solver for stage game \( \{Q'_t(s'), \ldots, Q'_N(s')\} \) (\( s' \) is the state at time \( t + 1 \)); that is, the \( Q \)-function will eventually converge to a Nash equilibrium value of the entire game.

3. Mean Field MARL

As the number of agents increases, the joint action space \( a \) becomes high dimensional. All agents act strategically and simultaneously learn their values over others actions, which make the learning of the standard \( Q \) function \( Q^t(s, a) \) in the previous section infeasible. To handle this, we parametrize the \( Q \)-function by only the pairwise local interactions:

\[
Q^t(s, a) = \frac{1}{N!} \sum_{k \in \mathcal{K}_j^t} Q^t(s, a^j, a^{k_j}),
\]

where \( \mathcal{K}_j^t \) is the set of neighbor agents for agent \( j \). Its size \( N! \propto |\mathcal{K}_j^t| \) grows proportionally to the number of agents, and so does the ratio depends on applications. It is worth noting that the pairwise approximation, while significantly reducing the complexity of the interactions among agents, still preserves global interactions between any pair of agents implicitly.
Mean Field Multi-Agent Reinforcement Learning

(Blume, 1993). Similar approaches in machine learning can be found such as in factorization machine (Rendle, 2012) and learning to rank (Cao et al., 2007).

3.1. Mean Field Approximation

We consider discrete action space, whereas a continuous version can be analogically derived. Specially, action \( a^j \) is a discrete categorical variable, which is represented as a one-hot encoding with each component indicating one of the \( M \) possible actions: \( a^j ∈ (a_1^j, ..., a_M^j) \). The pairwise interaction \( Q^j(s, a^j, a^k) \) can be approximated by the mean field theory (Stanley, 1971). Conveniently the one-hot action of each agent can be represented as a small fluctuation \( δa^k \) from the mean action within the neighborhood:

\[
a^k = \bar{a} + δa^k, \quad \text{where} \quad \bar{a} = \frac{1}{N^j} \sum_{k \in K^j} a^k.
\]  

(7)

Note that the mean action \( \bar{a} ≡ (\bar{a}_1, ..., \bar{a}_M) \) is equivalent to the multinomial distribution of actions from neighboring agents. With the first-order Taylor expansion, the pairwise \( Q \)-function is approximated as

\[
Q^j(s, a) = \frac{1}{N^j} \sum_{k \in K^j} Q^j(s, a^j, a^k)
\]

\[
≈ \frac{1}{N^j} \sum_{k \in K^j} \left[ Q^j(s, a^j, \bar{a}) + \nabla_a Q^j(s, a^j, \bar{a}) δa^k \right]
\]

\[
= Q^j(s, a^j, \bar{a}) + \nabla_a Q^j(s, a^j, \bar{a}) \frac{1}{N^j} \sum_{k \in K^j} δa^k
\]

\[
= Q^j(s, a^j, \bar{a}).
\]  

(8)

Note that in the second line of Eq. (8) we utilize the first-order approximation of \( Q^j \), where the accuracy improves when the number of neighbours grows large, since the mean value of the higher order terms approach zero. The multiple-agent interactions have been converted into those of two-agent interactions: a single agent and the mean agent from the neighbors.

The update rule for the mean field \( Q \)-function is defined as

\[
Q_{t+1}^j(s, a^j, \bar{a}) = (1 - \alpha_t) Q_t^j(s, a^j, \bar{a}) + \alpha_t \left[ r_t^j + \gamma v_t^j(a') \right]
\]  

(9)

where \( \alpha_t \) denotes the learning rate and the mean field value function is as

\[
v_t^j(s) = \sum_{a'} π_t(a'|s) \bar{Q}_t^j(s, a'),
\]

(10)

in which

\[
\bar{Q}_t^j(s, a') = E_{a^j, a^k \sim \pi_{t-1}} \left[ Q_t^j(s, a^j, \bar{a}) = \frac{1}{N^j} \sum_{k \notin j} a^k \right].
\]  

(11)

As shown in Eq. (10), we see that under the mean field approximation, the MARL problem is converted into the computation of a single agent’s best response with respect to the action distribution of other agents.

To discriminate from the Nash value function \( v^{\text{Nash}}(s) \), we refer the mean field value function defined in Eq. (10) as \( v^{\text{MF}}(s) = (v_1^{\text{MF}}(s), ..., v_N^{\text{MF}}(s)) \).

Based on the mean field value function, we finally define the mean field \( Q \)-operator as \( H_{\text{MF}}^Q \mathcal{Q} = (H_{\text{MF}}^Q Q^1, ..., H_{\text{MF}}^Q Q^N) \), and

\[
(H_{\text{MF}}^Q \mathcal{Q})(s, a) ≡ \mathbb{E}_{a^i \sim \pi_i} \left[ r(s, a) + \gamma v_i^{\text{MF}}(s') \right].
\]  

(12)

In fact, we can prove that \( H_{\text{MF}}^Q \) is a contraction mapping; that is, by updating the \( Q \)-function via the mean field operator \( H_{\text{MF}}^Q \), the mean field \( Q \)-learning will eventually converge to the Nash equilibrium under certain assumptions.

3.2. Implementation

In this section we describe the implementation logic of our proposed algorithm. We parameterize the \( Q \)-function and policy \( \pi \) by \( \phi \) and \( \theta \) respectively, and update parameter \( \phi \) according to Eq.(9). Once \( Q \)-function is updated, we improve the current policy \( \pi \). For on-policy reinforcement learning, we use Boltzmann strategy and actor-critic method (Konda & Tsitsiklis, 2000) to improve policy, presenting MF-Q (Algorithm 1 in Appendix A) and MF-AC (Algorithm 2 in Appendix A) respectively.

For agent \( i \), MF-Q can be trained by minimizing the loss function

\[
\mathcal{L}(\phi) = (y - Q_\phi(s, a', \bar{a}))^2,
\]  

(13)

where \( y = r + \gamma Q_\phi(s', (a')', \bar{a}') \) is the target. Differentiating \( \mathcal{L}(\phi) \) w.r.t the weights produces the following gradient,

\[
\nabla_\phi \mathcal{L}(\phi) = (y - Q_\phi(s, a', \bar{a})) \nabla_\phi Q_\phi(s, a', \bar{a}).
\]

(14)

The Critic of MF-AC follows the same update rule as above. The Actor can be trained by using the sampled policy gradient:

\[
\nabla_\theta J(\theta) ≈ \nabla_\theta \log \pi_\theta(s) Q_\phi(s, a', \bar{a}) |_{a=a'=\pi_\theta(s)}.
\]

(15)

Note that we require the policies of other agents to apply an update in Eq. 14. For off-policy learning, we can use DPG (Silver et al., 2014) for deterministic environment or standard \( Q \)-learning (Watkins & Dayan, 1992) for a discrete case. We iteratively execute parameter update for \( \phi \) and \( \pi \) until the \( Q \)-function converges.

3.3. Proof of Convergence

We prove the convergence of \( Q_\ast = (Q^1_\ast, ..., Q^N_\ast) \) under the MF-Q iterations to Nash equilibrium \( Q_\ast = (Q^1_\ast, ..., Q^N_\ast) \)
for learning agents. The proof is conducted through showing that under the main assumptions below, the mean field $Q$ operator $\mathcal{H}^{\text{MF}}$ of Eq. (12) is in fact a contraction mapping, and its fixed point is $Q^*$. We start by introducing the main assumptions:

**Assumption 1.** During training, each action-value pair will be visited infinitely often, and the reward is bounded by some constant $K$.

**Assumption 2.** Agent's policy is Greedy in the Limit with Infinite Exploration (GLIE). In the case of Boltzmann softmax policy, the temperature decays to the zero so that the policy becomes greedy on the $Q$-function in the limit.

We make further assumptions on the structure of the game:

**Assumption 3.** For every stage game $(Q_1^t(s),...,Q_N^t(s))$ encountered during training, for all $t$, $s$, and $j \in \{1,...,N\}$, only one of the two scenarios could happen: the Nash equilibrium $\pi = (\pi_1,...,\pi_N)$ is either (I) a global optimal point, i.e. $E_x[Q^t_j(s) - Q^t_i(s)] \geq 0, \forall \pi \in \Omega(\prod_i A_i^t)$, or (II) a saddle point, i.e. $E_x[Q^t_j(s)] \geq E_{x_i}[E_{x_{-i}}[Q^t_j(s)]] \geq E_{x_i}[E_{x_{-i}}[Q^t_i(s)]] \forall \pi \in \Omega(\prod_i A_i^t)$.

Note that Assumption 3 asks for a strong requirement on every individual stage game encountered during training. In practice, however, we find this is not necessary to hold in order for the learning algorithm to converge. This is in line with the empirical findings in Hu & Wellman (2003).

Our proof depends on the following two Lemmas:

**Lemma 1.** Under the Assumption 3, the Nash $Q$ operator defined in Eq. (5) is a rigorous contraction mapping on the complete metric space from $Q$, its fixed point is the Nash $Q$-value of the entire game, i.e., $\mathcal{H}^{\text{Nash}}_t Q^* = Q^*$.

**Proof.** See Theorem 17 in Hu & Wellman (2003).

**Lemma 2.** The random process $\{A_t\}$ in $\mathcal{R}$ defined as

$$ A_{t+1}(x) = (1 - \alpha_t(x)) A_t(x) + \alpha_t(x) F_t(x), $$

which converges to zero with probability 1 w.p.1 under the following assumptions:

1. $0 \leq \alpha_t(x) \leq 1$, $\sum_t \alpha_t(x) = \infty$, $\sum_t \alpha_t^2(x) < \infty$

2. $x \in \mathcal{X}$, the set of possible states is finite.

3. $E[|F_t(x)| |F_t|] \leq K (1 + ||A_t||^2 W)$, for constant $K > 0$.

Here $F_t$ is the filtration of an increasing sequences of $\sigma$-fields that include the history of the process. We assume that $\alpha_t, A_t, F_t \in \mathcal{F}_t$, and $||\cdot||_W$ is a weighted maximum norm.

**Proof.** This Lemma is proved by Jaakkola et al. (1994) (Theorem 1) and Szepesvári & Littman (1999) (Corollary 5). We include it here to stay self-contained.

In Lemma 2, by subtracting $Q_t(s, a)$ at both sides in Eq. (9) and comparing with Eq. (16), we can find in fact

$$ A_t(x) = Q_t(s, a) - Q_t(s, a), $$

$$ F_t(x) = r + \gamma v^{\text{Nash}}_{t+1}(s, a) - Q_t(s, a), $$

where $x = \{s_t, a_t\}$. $\alpha_t(i)$ can be regarded as the learning rate, and agent will only update the $Q$-function with the corresponding state $s_t$ and actions $a_t$ visited, i.e., $\alpha_t(s, a) = 0$ for $(s, a) \neq (s_t, a_t)$. Note that Lemma 2 suggests the convergence of $A_t(x)$ to zero, that means, if it holds, the current $Q$-function will asymptotically approximate the optimal $Q^*$.

One last piece before the main theorem is the below:

**Proposition 1.** Let the metric space be $\mathbb{R}^N$, and the metric be $d(a,b) = \sum_{i=0}^{N} |a^i - b^i|$, $a = \{a^i\}^N_i, b = \{b^i\}^N_i$. If the $Q$ function is Lipschitz continuous w.r.t. the input of $a^t$, then for sufficiently small temperature $\beta$, the operator

$$ B(a') = \exp \left( -\beta Q(s, a', \tilde{\pi}) \right) $$

is a contraction mapping. The proof is in Appendix due to the space limit.

**Theorem 1.** In finite-state stochastic game, the $Q_t$ values computed by the MF-$Q$ rule in Eq. (9) converges to the Nash $Q$-value $Q^* = (Q_1^*, ..., Q_N^*)$, of the Assumptions 1, & 2, 3, and condition 1 & 2 of Lemma 2 are met.

**Proof.** We denote the $\sigma$-field generated by the random variables in the experience of the stochastic game $\{s_t, a_t, r_{t-1}, ..., s_1, a_1, Q_0\}$ by $\mathcal{F}_t$. Given the fact that $\mathcal{F}_t$ is $\mathcal{F}_t$-measurable, thus both $A_t$ and $F_{t-1}$ are $\mathcal{F}_t$-measurable, which satisfies the measurability condition of Lemma 2.

We further need to prove $\mathcal{H}^{\text{MF}}$ operator satisfies conditions 3 & 4 to employ Lemma 2. We start from condition 3.

$$ F_t(s_t, a_t) = r_t + \gamma v^{\text{Nash}}_{t+1}(s_{t+1}) - Q^*(s_t, a_t) $$

$$ = r_t + \gamma v^{\text{Nash}}_{t+1}(s_{t+1}) - Q^*(s_t, a_t) $$

$$ + \gamma [v^R_{t+1}(s_{t+1}) - v^{\text{Nash}}_{t+1}(s_{t+1})] $$

$$ = [r_t + \gamma v^{\text{Nash}}_{t+1}(s_{t+1}) - Q^*(s_t, a_t)] + C_t(s_t, a_t) $$

$$ = F^{\text{Nash}}_t(s_t, a_t) + C_t(s_t, a_t) $$

(17)

In fact, we find $F^{\text{Nash}}_t(s_t, a_t)$ is the corresponding $F_t$ in Lemma 2 as if the convergent proof was about the Nash $Q$ learning algorithm. Based on Lemma 1, it is easy to know that $F^{\text{Nash}}_t(\cdot, \cdot)$ is a contraction mapping where the norm $\|\cdot\|$ is the maximum norm over $a$, thus we have, for all $t$,

$$ \|E[F^{\text{Nash}}_t(\cdot, \cdot)|\mathcal{F}_t]\|_\infty \leq \gamma \|Q - Q^*\|_\infty = \gamma \|A_t\|_\infty $$

In meeting the condition 3 of Lemma 2 now we have

$$ \|E[F_t(s_t, a_t)|\mathcal{F}_t]\| \leq \|F^{\text{Nash}}_t(s_t, a_t)|\mathcal{F}_t\| + \|C_t(s_t, a_t)|\mathcal{F}_t\| $$

$$ \leq \gamma \|A_t\| + \|C_t(s_t, a_t)|\mathcal{F}_t\|. $$

(18)
Mean Field Multi-Agent Reinforcement Learning

We are left to prove $c_t = \|C_t(s_t, a_t)\|_{F_t}$ converges to zero w.p.1. In fact, under Assumption 3, for each stage game, all the global optimal equilibrium point(s) share the same equilibrium value, so does any saddle-point equilibrium.

Case I: In each global equilibrium, according to the definition, all players get the same unique maximum value.

Case II: Assume the stage game $\{Q^f_j\}_N$ has two saddle-point equilibrium: $\pi$ and $\rho$, then for agent $j$, we have

\[
E_{\pi_j}[Q_{t-1}^f(s)] \leq E_{\pi_j}[Q_t^f(s)] ,
\]

\[
E_{\pi_j}[Q_{t-1}^f(s)] \leq E_{\rho_j}[Q_t^f(s)] .
\]

Combining them we have

\[
E_{\pi_j}[Q_{t-1}^f(s)] \leq E_{\rho_j}[Q_{t-1}^f(s)].
\]

By the definition of saddle point, reversing the order of $\pi$ and $\rho$, the formula still holds; thus the equilibria to agent $i$ under both saddle-point equilibrium must be the same:

\[
E_{\pi_i}[Q_{t-1}^f(s)] = E_{\rho_i}[Q_{t-1}^f(s)].
\]

Given the Proposition 1 that the policy of mean field $Q$-function is a contraction mapping, and that all global/saddle points share the same Nash value in each stage game, $v^{\text{MF}}$ value will therefore converge to $v^{\text{ash}}$ value asymptotically. Condition 3 is thus satisfied.

For condition 4, based on the condition 3 just proved, $\mathcal{H}^{\text{MF}}$ is a contraction mapping, i.e., $\mathcal{H}^{\text{MF}}Q_t = Q_t$, thus we have:

\[
\text{var}[F_t(s_t, a_t)|F_{t-1}] = E[(r_t + \gamma v^{\text{MF}}(s_{t+1}) - Q_t(s_t, a_t))^2]
\]

\[
= E[(r_t + \gamma v^{\text{MF}}(s_{t+1}) - H^{\text{MF}}(Q_t))^2]
\]

\[
\text{var}[r_t + \gamma v^{\text{MF}}(s_{t+1})|F_{t-1}]
\]

\[
\leq K(1 + \|A_t\|^2_{\mathcal{W}})
\]

In the last step, we apply the Assumption 1 that the reward is always bounded by some constant. Finally, by meeting both condition 3 & 4, according to Lemma 2, $A_t$ converges to zero w.p.1, i.e., $Q_t$ converges to $Q$, w.p.1.

Apart from convergence, we also discuss the Rationality (Bowling & Veloso, 2001; 2002) of the MF-Q algorithm, due to the space limit, we leave it in the Appendix.

4. Related Work

We continue our discussion on related work started in Section 1 and make comparisons with existing techniques in a greater scope. Our work follows the same direction as from (Littman, 1994; Hu & Wellman, 2003; Bowling & Veloso, 2002) in adapting a Stochastic Game (van der Wal, 1980) in the MARL formulation. Specifically, Littman (1994) addressed two-player zero-sum stochastic games by introducing a “minimax” operator in $Q$-learning, whereas Hu & Wellman (2003) extended it to the general-sum case by learning a Nash equilibrium in each stage game and considering a mixed strategy. Nash-Q learning is guaranteed to converge to Nash strategies under the (strong) assumption that there exists equilibrium for every stage game, defined by the $Q$-functions. In the situation where agents can be identified as either "friends" or "foes", one can simply the solution by alternating between fully cooperative and zero-sum learning (Littman, 2001). Moreover, Littman & Stone (2005) and de Cote & Littman (2008) draw on the folk theorem and acquired a polynomial-time Nash equilibrium algorithm for repeated stochastic games. Bowling & Veloso (2002) varied the learning rate to improve the convergence.

The recent treatment of MARL was using deep neural networks as a function approximator. For instance, in addressing the non-stationary issue in MARL, various solutions have been proposed including neural-based opponent modeling (He & Boyd-Graber, 2016), policy parameters sharing (Gupta et al., 2017) etc. Researchers have also adopted the paradigm of centralized training with decentralized execution for multi-agent policy-gradient learning: BICNET (Peng et al., 2017), COMA (Foerster et al., 2016) and MADDPG (Lowe et al., 2017a), which allow the centralized critic $Q$-function augmented with actions of other agents, and the actor needs only local observation history to optimize agent’s policy.

The above MARL approaches limit their studies mostly to a few agents. As the number of agents grows, not only the input space of $Q$ grows linearly, but most critically the accumulated noises by the exploratory actions of other agents make the $Q$-function learning no longer feasible. Our work addresses the issue by making use of mean field approximation (Stanley, 1971) over the joint action space. The parameters of the $Q$-function is independent of the number of agents as it transforms multiple agents interactions into two entities interactions (single agent vs. a distribution of other agents). This would also effectively alleviate the exploratory noise (Colby et al., 2015) caused by many other agents and allow each agent to effectively determine which actions are beneficial or not, as we have demonstrated from one of our experiments.

Our work is also closely related to the recent development of mean field game (MFG) (Lasry & Lions, 2007; Huang et al., 2006; Weintraub et al., 2006). MFG studies population behaviors resulting from the aggregations of decisions taken from individuals. Mathematically, the dynamics are governed by a set of two stochastic differential equations that model the backward dynamics of individual’s value function, and the forward dynamics of the aggregate distribution of agent population. Despite that the backward equation equivalently describes what Bellman equation indicates in MDP, the primarily goal for MFG is rather for a model-based planning/control and to infer the movements of the individual density through time. We also employ the mean field approximation (Stanley, 1971) in physics, but our
work is different in that we focus on a model-free solution of learning optimal actions when the dynamics of the system (environment) and the reward function are unknown. Very recently, Yang et al. (2017) built a connection between MFG and RL. Their focus is, however, on inverse RL in order to learn both the reward function and the forward dynamics of the MFG from the policy data, whereas our goal is to form a computable Q-function under the framework of temporal difference learning.

5. Experiments
We analyze and evaluate our algorithms by three different scenarios, including two stage games (Busoniu & De Schutter), namely Gaussian Squeeze and Ising Model, and a mixed cooperative-competitive battle game.

5.1. Gaussian Squeeze

5.1.1. Environment
In the Gaussian Squeeze problem (GS) (Holmes-Parker et al., 2014), $N$ homogeneous agents determine their individual actions $a^j$ to jointly optimize the sum $x = \sum_{j=1}^{N} a^j$ for resource allocation. Each agent has 10 action choices, i.e., integer value from 0 to 9 as the quantity of resource utilized by this agent. This problem is similar to traffic congestion domains, where each agent is a traffic controller of a single intersection and wants to send $a^j$ vehicles into a shared main route. Controllers are expected to coordinate with each other to make the full use of the main route while avoiding too much traffic. The system objective is defined as $G(x) = x e^{-\frac{(x-\mu)^2}{2\sigma^2}}$, where $\mu$ and $\sigma$ is the predefined mean and standard deviation of the system objective’s Gaussian respectively. The goal of agents is to learn to allocate system resources efficiently, avoiding over- or under-utilization. This GS problem is ideal for an ablation study on the impact of multi-agent exploratory noises toward the learning (Colby et al., 2015).

5.1.2. Model Settings
We implement MF-Q and MF-AC following the framework of centralized training (shared Q) with decentralized execution (independent policy). We compare them with 4 baseline models: (1) Independent Learner (IL) (Watkins & Dayan, 1992), a decentralized Q-Learning algorithm that agents only observe local actions and update their Q-values without regard to the actions performed by other agents; (2) Frequency Maximum Q-value (FMQ) (Kapetanakis & Kudenko, 2002), a modified IL which increases the Q-values of actions that frequently produced good rewards in the past; (3) Recursive Frequency Maximum Q-value (Rec-FMQ) (Matignon et al., 2012), an improved and robust version of FMQ which recursively computes the occurrence frequency using a linear interpolation to evaluate and choose actions; and (4) Multi-agent Actor-Critic (MAAC), a variant of MADDPG architecture (Lowe et al., 2017b) for the discrete action space in the task. All models use the multilayer perceptron (MLP) as function approximator. The full descriptions of implementation details are provided in Appendix B.1.

5.1.3. Results
Fig. 1 illustrates our results for different number of agents in the GS environment with $\mu = 400$ and $\sigma = 200$ with three numbers of agents, i.e., $N = 100, 500, 1000$, for 3 levels of congestion settings respectively. Fig. 1a shows that all models perform well in the small GS domain. As the number of agents becomes larger, Figs. 1b and 1c show MF-Q and MF-AC are still capable of learning the optimal allocation effectively after a few iterations, whereas all the baselines, IL, FMQ, Rec-FMQ and MAAC, fail to learn at all. This advantage is largely owing to the mean field methods awareness of other agents’ actions, while still keeping the interactions among agents relatively small, which reduces the effect of exploratory behaviors of the other agents. MF-Q converges quicker than MF-AC as it takes time for the Actor to learn an optimal policy. Both FMQ and Rec-FMQ fail to reach good performance because agents cannot distinguish rewards received for the same action due to various behaviors of other agents and stochastic rewards, and are thus unable to update their own Q-values w.r.t. the actual contributions. It is worth noticing that MAAC (all others actions as independent inputs in the $Q$ function) is inefficient in learning when the number of agents becomes large. It fails to handle the non-aggregated noises from the exploration of many other agents.
Mean Field Multi-Agent Reinforcement Learning

Figure 3: Performance against training steps in 20x20 grid Ising model.

5.2. MARL for Ising Model

5.2.1. Environment

In statistical mechanics, the Ising model is a mathematical model of ferromagnetism (Ising, 1925). It is also proved to be successful in numerous applications, particularly in sociophysics (Galam & Walliser, 2010). The typical mean field Ising model (Stanley, 1971) can iteratively solve \( \langle a^j \rangle = \sum_a a^j P(a) \) for every site \( j \) on the condition that the reward mapping function is given. See Eq. (23) in Appendix B.2 for details. Our mean field MARL, however, is different as the algorithm does not need to know the reward function, but learns it over time.

To fit our case, we turn the Ising model into a stage game where the reward for each site (agent) is as \( r^j = h^j a^j + \tau \sum_{k \in K^j} a^j a^k \), where \( K^j \) is the set of nearest neighbors of site \( j \), \( h^j \in \mathbb{R} \) is the external field affecting site \( j \), and \( \tau \in \mathbb{R} \) is an interaction term determines how much the sites tend to align in the same direction. Unlike the typical setting above, each site does not know the reward function exactly, but aims to maximize its received reward by changing its individual policy \( \pi^j \) to choose the spin state: up or down.

In addition to the observed reward, the order parameter (OP) (Stanley, 1971) is also a commonly used evaluation metric for Ising model. OP is defined as \( \xi = \frac{\langle N^\uparrow - N^\downarrow \rangle}{N} \), where \( N^\uparrow \) represents the number of sites spinning up, and vice versa. The closer the OP is to 1, the more orderly the system.

5.2.2. Model Settings

To prove the correctness of MF-Q value, we implement MCMC methods (Binder et al., 1993) to simulate the Ising model and provide the ground truth for our proposed method. MCMC relies on repeated random sampling to obtain numerical results and is often used in physical and mathematical domains. The full descriptions of MCMC and MF-Q for Ising model are provided in Appendix B.2. Notice that we do not know exactly the mapping function in Eq. (23), but rather using Temporal Difference learning to approximate \( \langle a^j \rangle \) during learning procedure. One of our learning goals is to obtain the accurate approximation of \( \langle a^j \rangle \). Once it is accurately approximated, we should be able to converge to the simulation result of Ising model provided by MCMC.

5.2.3. Results

Correctness of MF-Q Value. Fig. 2 illustrates the order parameter at equilibrium w.r.t. the Ising Model temperature setting in 20x20 grid Ising model. As shown on the graph, MF-Q can converge to a similar OP value with MCMC under different temperature settings, proving the correctness of our algorithm. Also, MF-Q finds a similar Curie temperature as MCMC, which is around \( \tau = 1.2 \).

Learning Ability. Fig. 3 illustrates the Mean Squared Error between learned Q-value and reward target (mean field) in 20x20 grid Ising model w.r.t. training steps. As one can observe, MF-Q is able to learn the target well under low temperature settings (Fig. 3a). Around the Curie temperature, the environment will force the site to choose spin state with too much randomness, resulting in a lower OP and higher MSE (Fig. 3b).

Convergence Equilibrium. Fig. 4 shows some example results at equilibrium from our simulation. Most of the sites choose the same spinning pattern in both MCMC and MF-Q under a low temperature (\( \tau = 0.9 \)). As the temperature rises, some sites start to change its spinning pattern and some patches are formed as spontaneous magnetization with the constraint of neighboring sites and system energy (\( \tau = 1.2 \)). This phenomenon is mostly observed around the Curie temperature. After passing the Curie temperature, the system becomes totally disordered due to large thermal fluctuations, resulting in a random spinning situation.

(b) chasing and cooperation

Figure 6: Performance of algorithms on winning rate, total reward. Each bar cluster shows the index of a set of competing algorithms, and a higher index is better.

(a) MF-AC learning curve
(b) MF-Q learning curve

Figure 7: It can be seen from the above two figures that the MF-AC converges much slower than that of MF-Q.

5.3. Mixed Cooperative-Competitive Battle Game

5.3.1. Environment

The Battle game in the OpenSource MAgent system (Zheng et al., 2017) is a Mixed Cooperative-Competitive scenario with two armies fighting against each other in a grid world, shown in Fig. 5. In our settings, each army consists of 64 homogeneous agents. In each timestep, each agent takes actions to either move to or attack one of the 8 neighbor grids. The goal of each army is to get more rewards by collaborating teammates and eliminating all opponents. We adopt the default setting, i.e., the reward is -0.005 for every move, 0.2 for attacking an enemy agent, 5 for killing an enemy agent, -0.1 for attacking a blank grid, and -0.1 for being attacked or killed.

5.3.2. Model Settings

Our MF-Q and MF-AC are compared with the baselines that are successful on the MAgent platform (Zheng et al., 2017). In the battle game there are a large number of agents, each of which can only take in observation within its local view, thus the Q-function involves different numbers of neighbor agents. This makes MADDPG not feasible.

As demonstrated in our previous experiment (Figure 1), a variant MAAC also fails when the agent number is large. We thus exclude MADDPG as a baseline, while focusing on the comparison between mean field methods (MF-Q, MF-AC) and their non-mean field counterparts, i.e., independent Q-learning (IL) and advantageous actor critic (AC).

5.3.3. Results

We get all models with 2000 rounds self-play training, then use them for cross-comparative experiments. Fig. 6 shows the result of winning rate and the total reward over 2000 rounds cross-comparative experiments. It is evidence that on all the metrics mean field methods, i.e., MF-Q and MF-AC, largely outperform the corresponding baselines, i.e., IL and AC respectively, which shows the effectiveness of the mean field approximation.

In addition, IL performs much better than AC, and although worse than its mean field counterpart MF-Q, better than MF-AC. This is consistent with the findings in in the Gaussian Squeeze game (in Figure 1) that IL converges quicker than AC. This might imply the effectiveness of off-policy learning with shuffled buffer replay in many-agent RL toward a more stable learning process. The Q-learning family tends to introduce an positive bias (Hasselt, 2010) by using the maximum action value as an approximation for the maximum expected action value; we find that such overestimation can be beneficial for each single agent to find the best response to others even though the environment itself is still varying. We further test the situation when the agent number is 8 for each army, where MF-AC achieves 58% winning rate and get total rewards of 34.4 while AC achieves 42% winning rate and get total rewards of 31.6. We see that (i) when the agent number is small, MF-AC slightly outperforms AC mainly because of the higher capacity of the Q-network; (ii) when the agent number gets larger, MF-AC starts to significantly outperform AC, which verifies the mean field methods work particularly better for scenarios with a larger number of agents.

6. Conclusions

In this paper, we have developed mean field reinforcement learning that tackles the problem of intractable computation and high dynamics of interactions among a large number of agents. With mean field theory, we approximated the Q-function by using the distribution of the actions from other agents as inputs in order to balance the complexity of the interactions modeled and the learning ability. It is done by iteratively learning the best responded actions on the condition of the distribution of other agents’ actions, which is subsequently updated each time a new action policy is obtained. We provided our theoretical analysis on our MF-Q learning convergence. The results from three different
Mean Field Multi-Agent Reinforcement Learning

types of environments have shown the effectiveness of our approaches when the number of agents is large.

There are two interesting future directions. The first is to investigate the local and global communication mechanisms, and a more appropriate network architecture for mean field $Q$-functions in such a setting. The second is to construct a Bayesian solution to embed the prior knowledge of agents optimal policy into the distribution of the agent population.

A. Detailed Mean Field Reinforcement Learning Algorithms

Here we provide the pseudo code for Mean Field Q-learning (MF-Q) in Algorithm 1 and Mean Field Actor-Critic (MF-AC) in Algorithm 2.

**Algorithm 1** Mean Field Q-learning (MF-Q)

```
while training not finished do
    for agent \( j \) = 1 to \( N \) do
        Sample a random minibatch of \( K \) samples \((s, a, r, s', \hat{a})\) from \( \mathcal{D} \)
        Set \( y = r^j + \gamma Q_{\phi^-}(s^j', (a^j)', \hat{a}') \)
        Update Q-network by minimizing the loss \( \mathcal{L}(\phi) = \frac{1}{K} \sum_K (y - Q_{\phi}(s^j, a^j, \hat{a}))^2 \)
    end for
    Update target network parameters for each agent \( j \):
    \[
    \phi^j_\perp \leftarrow \tau \phi^j_\perp + (1 - \tau) \phi^j \\
    \theta^j_\perp \leftarrow \tau \theta^j_\perp + (1 - \tau) \theta^j
    \]
end while
```

**Algorithm 2** Mean Field Actor-Critic (MF-AC)

```
while training not finished do
    for agent \( j \) = 1 to \( N \) do
        Sample a random minibatch of \( K \) samples \((s, a, r, s', \hat{a})\) from \( \mathcal{D} \)
        Set \( y = r^j + \gamma Q_{\phi^-}(s^j', (a^j)', \hat{a}') \)
        Update critic by minimizing the loss \( \mathcal{L}(\phi) = \frac{1}{K} \sum_K (y - Q_{\phi}(s^j, a^j, \hat{a}))^2 \)
        Update actor using the sampled policy gradient:
        \[
        \nabla_a \mathcal{J}(\theta^j) \approx \frac{1}{K} \sum_K \nabla_a \log \pi^j_\phi((s^j)', (a^j)', \hat{a}')) |_{(a^j)'=\pi^j_{\theta^-}(s^j')} \]
    end for
    Update target network parameters for each agent \( j \):
    \[
    \phi^j_\perp \leftarrow \tau \phi^j_\perp + (1 - \tau) \phi^j \\
    \theta^j_\perp \leftarrow \tau \theta^j_\perp + (1 - \tau) \theta^j
    \]
end while
```

B. Experiment Details

B.1. Gaussian Squeeze

Il, FMQ, Rec-FMQ and MF-Q all use a three-layer MLP to approximate \( Q \)-value. All agents share the same \( Q \)-network for each experiment. The shared \( Q \)-network takes an agent embedding as input and computes \( Q \)-value for each candidate action. For MF-Q, we also feed in the action approximation \( \hat{a} \). We use the Adam optimizer with a learning rate of 0.00005 and \( \epsilon \)-greedy exploration unless otherwise specified. For FMQ, we set the exponential decay rate \( s = 0.006 \), start temperature \( \text{max}_\text{temp}=1000 \) and FMQ heuristic \( c = 5 \). For Rec-FMQ, we set the frequency learning rate \( \alpha_f = 0.01 \).
Algorithm 3 MCMC in Ising Model

initialize spin state \( a \in \{-1, 1\}^N \) for \( N \) sites

while training not finished do
    randomly choose site \( j \in \mathcal{I}_N \)
    flip the spin state for site \( j \): \( (a^j)' \leftarrow -a^j \)
    compute neighbor energy \( E(a, h) = -\sum_j (h_j a^j + \frac{1}{2} \sum_{k \in \mathcal{K}^j} a^j a^k) \) for \( a^j \) and \( (a^j)' \)
    randomly choose \( \epsilon \sim U(0, 1) \)
    if \( \exp((E(a^j, h) - (E(a^j)', h))/\tau) > \epsilon \) then
        \( a^j \leftarrow (a^j)' \)
    end if
end while

MAAC and MF-AC use the Adam optimizer with a learning rate of 0.001 and 0.0001 for Critics and Actors respectively, and \( \tau = 0.01 \) for updating the target networks. We share the Critic among all agents in each experiment and feed in an agent embedding as extra input. Actors are kept separate. The discounted factor \( \gamma \) is set to be 0.95 and the mini-batch size is set to be 200. The size of the replay buffer is \( 10^6 \) and we update the network parameters after every 500 samples added to the replay buffer.

For all models, we use the performance of the joint-policy learned up to that point if learning and exploration were turned off (i.e., take the greedy action w.r.t. the learned policy) to compare our method with the above baseline models.

B.2. Ising Model

An Ising model is defined as a stateless system with \( N \) homogeneous sites on a finite square lattice. Each site determines their individual spin \( a^j \) to interact with each other and aims to minimize the system energy for a more stable environment. The system energy is defined as

\[
E(a, h) = -\sum_j (h_j a^j + \frac{1}{2} \sum_{k \in \mathcal{K}^j} a^j a^k)
\]  

(20)

where \( \mathcal{K}^j \) is the set of nearest neighbors of site \( j \), \( h^j \in \mathbb{R} \) is the external field affecting site \( j \), and \( \lambda \in \mathbb{R} \) is an interaction term determines how much the sites tend to align in the same direction. The system is said to reach an equilibrium point when the system energy is minimized, with the probability

\[
P(a) = \frac{\exp(-E(a, h)/\tau)}{\sum_a \exp(-E(a, h)/\tau)}.
\]  

(21)

where \( \tau \) is the system temperature. When the temperature rises beyond a certain point (the Curie temperature), the system can no longer keep a stable form and a phase transition happens. As the ground-truth is known, we would be able to evaluate the correctness of the \( Q \)-function learning when there is a large body of agents interacted.

The mean field theory provides an approximate solution to \( \langle a^j \rangle = \sum_a a^j P(a) \) through a set of self-consistent mean field equations

\[
\langle a^j \rangle = \frac{\exp(-h^j a^j + \lambda \sum_{k \in \mathcal{K}^j} \langle a^k \rangle)/\tau)}{1 + \exp(-h^j a^j + \lambda \sum_{k \in \mathcal{K}^j} \langle a^k \rangle)/\tau)}.
\]  

(22)

which can be solved iteratively by

\[
\langle a^j \rangle^{(t+1)} = \frac{\exp(-h^j a^j + \lambda \sum_{k \in \mathcal{K}^j} \langle a^k \rangle^{(t)}/\tau)}{1 + \exp(-h^j a^j + \lambda \sum_{k \in \mathcal{K}^j} \langle a^k \rangle^{(t)}/\tau)}.
\]  

(23)

where \( t \) represents the number of iterations.

To learn an optimal joint policy \( \pi^* \) for Ising model, we use the stateless \( Q \)-learning with mean field approximation (MF-Q), defined as

\[
Q'(a^j, \bar{a}) \leftarrow Q'(a^j, \bar{a}) + \alpha (r - \bar{Q}'(a^j, \bar{a})],
\]  

(24)
where the mean $\bar{a}$ is given as the mean $\langle a' \rangle$ from the last time step, and the individual reward is

$$ r^j = h^j a^j + \frac{\lambda}{2} \sum_{k \in A^j} a^k. \quad (25) $$

To balance the trade-off between exploration and exploitation under low temperature settings, we use a policy with Boltzmann exploration and a decayed exploring temperature. The temperature for Boltzmann exploration of MF-Q is multiplied by a decay factor exponentially through out the training process.

Without loss of generality, we assume $\lambda > 0$, thus neighboring sites with the same action result in lower energy (observe higher reward) and are more stable. Each site should also align with the sign of external field $h^j$ to reduce the system energy. For simplification, we eliminate the effect of external fields and assume the model to be discrete, i.e., $\forall j \in N, h^j = 0, a^j \in \{-1, 1\}$.

We simulate the Ising model using Metropolis Monte Carlo methods (MCMC). After initialization, we randomly change a site’s spin state and calculate the energy change, select a random number between 0 and 1, and accept the state change only if the number is less than $e^{-\frac{\beta E}{T}}$. This is called the Metropolis technique, which saves computation time by selecting the more probable spin states.

### B.3. Battle Game

IL and MF-Q have almost the same hyper-parameters settings. The learning rate is $\alpha = 10^{-4}$, and with a dynamic exploration rate linearly decays from $\gamma = 1.0$ to $\gamma = 0.05$ during the 2000 rounds training. The discounted factor $\gamma$ is set to be 0.95 and the mini-batch size is 128. The size of replay buffer is $5 \times 10^5$.

AC and MF-AC also have almost the same hyper-parameters settings. The learning rate is $\alpha = 10^{-4}$, the temperature of soft-max layer is $\tau = 0.1$. And the coefficient of entropy in the total loss is 0.08, the coefficient of value in the total loss is 0.1.

### C. Details of MF-Q

#### Proposition 1.

Let the metric space be $\mathbb{R}^N$, and the metric be $M(a, b) = \sum_j |a^j - b^j|, \forall a = \{a^j\}_1^N, b = \{b^j\}_1^N$. If the $Q$ function is Lipschitz continuous w.r.t. the input of $a^j$, then for sufficiently small temperature $\beta$, the operator

$$ B(a^j) = \frac{\exp (-\beta Q(s, a^j, \bar{a}))}{\sum_{a^j \in A^j} \exp (-\beta Q(s, a^j, \bar{a}))} $$

is a contraction mapping. The proof is in Appendix due to the space limit.

**Proof.** Following the contraction mapping theorem (Kreyszig, 1978), in order to be a contraction, the operator has to satisfy:

$$ M(B(a), B(b)) \leq \alpha M(a, b), \forall a, b $$

where $0 \leq \alpha < 1$.

Here we start from binary case and then adapt to the general multinomial case. We first rewrite $B(a^j)$ as:

$$ B(a^j) = 1 - \frac{1}{1 + \exp (-\beta Q(s, a^j, \bar{a}))}. $$

Then we have:

$$ |B(a^j) - B(b^j)| = \left| \frac{1}{1 + e^{-\beta Q(s, a^j, \bar{a})}} - \frac{1}{1 + e^{-\beta Q(s, b^j, \bar{a})}} \right| $$

$$ = \left| \frac{\beta e^{-\beta Q_0}}{(1 + e^{-\beta Q_0})^2} \right| |Q(s, a^j, \bar{a}) - Q(s, b^j, \bar{a})| $$

$$ \leq \frac{1}{4T} \cdot |Q(s, a^j, \bar{a}) - Q(s, b^j, \bar{a})| $$

$$ \leq \frac{1}{4T} \cdot K \cdot |a^j - b^j| $$

$$ \leq \frac{1}{4T} \cdot \sum_{k \in A^j} |a^k - b^k| $$

$\triangleq \frac{1}{4T} \cdot K \cdot M(a, b) \quad (26)$
In the 2nd equation, we apply the mean value theorem in Calculus: \( \exists x_0 \in [x_1, x_2], \text{s.t.,} \ f(x_1) - f(x_2) = f'(x_0)(x_1 - x_2) \). In the 3rd equation we use the maximum value for \( e^{-\beta Q_0} / (1 + e^{-\beta Q_0})^2 = 1/4 \) when \( Q_0 = 0 \). In the last equation we apply the Lipschitz constraint in the assumption where constant \( K \geq 0 \). Finally, we have:

\[
\mathcal{M}(B(a), B(b)) \leq \frac{1}{4T} \cdot K \cdot \sum_j |a^j - b^j|
\]

\[
= \frac{K}{4T} \mathcal{M}(a, b)
\]

In order for the contraction to hold, \( T > \frac{K}{4} \). In other words, when the action space is binary for each agent, and the temperature is sufficiently large, the mean field procedure converges.

This proposition can be easily extended to multinomial case by replacing binary variable \( a^j \) by a multi-dimensional binary indicator vector \( a^j \), on each dimension, the rest of the derivations would remain essentially the same.

C.1. Discussion on Rationality

In aligned with (Bowling & Veloso, 2001; 2002), we argue that to better evaluate a multi-agent learning algorithm, on top of the convergence guarantee, discussion on property of Rationality is also needed.

**Property 1.** *(also see (Bowling & Veloso, 2001; 2002)) In an N-agent stochastic game defined in this paper, given all agents converge to stationary policies, if the learning algorithm converges to a policy that is a best response to the other agents' policies, then the algorithm is Rationale.*

Our mean field Q-learning is rational in that Eq. (6) converts many agents interactions into two-body interactions between a single agent and the distribution of other agents actions. When all agents follow stationary policies, their policy distribution would be stationary too. As such the two-body stochastic game becomes an MDP, and the agent would choose a policy (based on Assumption 2) which is the best response to the distribution of other stationary policies. As agents are symmetric in our case, they all the best response to the distributions, therefore are rational.
