We uncover a novel and robust phenomenon that causes the gradual self-replication of spatiotemporal Kerr cavity patterns in cylindrical microresonators. These patterns are inherently synchronised multi-frequency combs. Under proper conditions, the axially-localized nature of the patterns leads to a fundamental drift instability that induces transitions amongst patterns with a different number of rows. Self-replications, thus, result in the stepwise addition or removal of individual combs along the cylinder’s axis. Transitions occur in a fully reversible and, consequently, deterministic way. The phenomenon paves forward a novel paradigm for Kerr frequency comb formation and reveals important insights into the physics of multi-dimensional nonlinear patterns.

PACS numbers:

The demonstration of a microresonator temporal soliton [1] and its subsequent stabilization [2,3] yielded and strongly boosted a wide range of applications of the associated stable frequency combs, such as frequency synthesis [4], spectroscopy [5], communications [6], and ranging [7], amongst many others (see, e.g., Refs. [8–10] for reviews). Aside from the widely employed single soliton states, the interest in other nonlinear waves such as Turing rolls is also growing rapidly as these waves are also very useful and may result in more efficient frequency comb generation [11–17]. Nevertheless, ongoing research on microresonator frequency combs remains strongly focused on essentially one-dimensional geometries, while potential advantages or qualitatively new ways to control and manipulate combs in multi-dimensional cavity geometries are not yet clearly identified.

In this Letter, we show that cylindrical Kerr microresonators, the natural two-dimensional extension of microrings [see Fig.1(a)], offer a remarkably robust mechanism to replicate and erase frequency combs along the axial direction. Each comb corresponds to a row of a spatiotemporal hexagonal pattern constituted by a periodic arrangement of solitonic pulses, so that the N-row spatiotemporal patterns localized along the axial direction are regarded as N-frequency comb states [c.f. Fig.1]. Individual combs are added or removed one by one in a step-wise deterministic way solely by tuning the width of the external laser pump beam. A powerful feature of the multi-comb states introduced here is that all combs tend to be identical to each other, thus matching among their free spectral range (FSR) occurs naturally, a property that is of great importance in the areas of high precision dual-comb spectroscopy [18], ultra-fast communications [19], and radio-frequency (RF) links [20]. In addition, such combs are inherently synchronised, which is fundamentally attractive [20] and may be beneficial for imaging applications requiring many combs [21]. In practice, multi-frequency comb states may be realised with microrods [22], pumped from rectangular waveguide or flattened fibers, or integrated microcylinders [23] coupled to integrated waveguides.

From a fundamental standpoint, the effect uncovered here is related to the phenomenon of pattern self-replication, which typically manifests as spot multiplications in reaction-diffusion systems [24,25] or pattern expansions in thermoconvection [27]. Self-replications include the symmetry-preserving transformations occurring within a given pattern family, as is the case here, in contrast to symmetry transformations, widely studied in optics and other contexts [28,30]. Replication phenomena are till date regarded as uncontrollable expansions [31], the taming of which represents a fundamental cornerstone yet to be achieved. In sharp contrast with previously known mechanisms [27,31], we show that the spatiotemporal patterns emerging after addition or removal of the entire new rows remain locked. The key ingredients for such transformations are the existence of drift instability and intertwined families of non-linear waves – rather general features of dissipative systems. These two features simultaneously present in our system enable stepwise self-replications and self-erasures of the multi-frequency comb states. Also, our findings are important for the fundamental understanding of pattern transformations and the physics of boundary effects such as stabilization [32] and geometrical frustration [29].

Applying the modal expansion approach [32,34] to a cylindrical microresonator, in which light orbits around its cross-section and diffracts along its axis [c.f. Fig.1(a)], yields the generalised damped-driven nonlinear
δiσ graded the practical usefulness of our results [see discussion of central importance for this Letter, i.e., the points where instabilities typically dominate in 2D (43)]. Amongst all possible pattern solutions of Eq. (1), the patterns we address exist with anomalous dispersion along x and z, easily attainable with micro-cylinders. Dispersion along x is readily controlled via the pump’s frequency and wall width, and dispersion along z is already anomalous unless modal interactions are specifically engineered (39).

FIG. 1: (a) Sketch of the driven micro-cylinder. (b), (c) snaking diagrams of pattern families $P_{\text{odd}}$ and $P_{\text{even}}$ on the ($\delta, U$) plane for $\sigma_z = 15$, $\sigma_z = 55$, respectively. Thick traces denote stability. Dots in (c) correspond to the profiles, $|\psi(x, z)|$, shown in insets (i) – (viii). Panels’ areas span over $x \in [-16, 16]$ (full circumference, $2\pi R$), $z \in [-20, 20]$. Here, $h_0 = \xi(x) = 1$. Scaling: $\Delta \delta = 0.1 \leftrightarrow 15.6$ MHz, $\sigma_z = 10 \leftrightarrow 4.9$ mm, $\Delta z = 40 \leftrightarrow 1.96$ cm, $h = 1 \leftrightarrow 46$ mW/mm.

Schrödinger equation (33, 36):

$$\partial_t \psi = \frac{i}{2} \left[ \partial_x^2 + \partial_z^2 \right] \psi - [1 + i\delta] \psi + i|\psi|^2\psi + ih(z, x, t),$$

$$h = h_0 e^{-x^2/\sigma_x^2} \xi(x, t),$$

accounting, respectively, for dispersion, diffraction, losses (unity), cavity-laser detuning, Kerr nonlinearity, and pump (see Supplemental Material for model scaling and derivation (37)). Similar models can be used to study comb formation in micro-bottles (38). Here, we are primarily concerned with the effects arising in the multifrequency comb states due to a variable pump localisation along z [c.f., Figs. 1(ii)]. However, realistic driving beams will typically couple to a relatively small region of the cylinder’s circumference [c.f. Fig. 1(a)], which is at rest in the lab frame. Thus the intracavity field, $\psi$, describing circulating state and the localised pump, $h$, have a huge velocity mismatch $\sim c$. In order to take into account the dynamical effects introduced by their relative motion, which could have potentially degraded the practical usefulness of our results [see discussion around Figs. 3(i), we will also account for pump localisation in $x$ through the function $\xi(x, t) \equiv \sum_{m=-\infty}^{\infty} \exp(-|x - m\Delta x| - v_g t/\sigma_z^2)$, where $\Delta x$ is the normalised circumference, $x \in [-\Delta x/2, +\Delta x/2)$, and $v_g$ is the normalised group velocity at the pump frequency (37). Below, we present our results in normalised units, but we provide the link to a reference geometry, consisting of a hollow silica glass cylinder of $R = 200 \mu$m radius, wall thickness $\approx 1 \mu$m, and quality factor $Q \approx 7.6 \times 10^6$, pumped at $\lambda_p = 1.55 \mu$m. For the sake of estimates only, we considered the pump as a cw state at $\lambda_p = 1.55 \mu$m propagating through a rectangular buswaveguide with a gap of 300 nm with the cylinder. The pump values will be translated into power per mm along the $z$ direction.

The patterns we address exist with anomalous dispersion along $x$ and $z$, easily attainable with micro-cylinders. Dispersion along $x$ is readily controlled via the pump’s frequency and wall width, and dispersion along $z$ is already anomalous unless modal interactions are specifically engineered (39).

Amongst all possible pattern solutions of Eq. (1), we focus on hexagonal patterns (40) due to their dominant relative stability (41, 42). Hereafter, $P_{\text{N}}$ denotes hexagonal patterns with $N$ rows along $z$ and fixed separation $x_p = 32/7$ between spots along $x$ [c.f. Figs. 1(i)-(viii)]. Stationary patterns, $P_{\text{S}}$, and their stability are computed by imposing $\partial_t \psi = 0$ and assuming uniform in $x$ pump ($\xi(x, t) = 1$). Figures 1(b), (c) show the existence and stability branches as norm $U \equiv \int_0^{2\pi} dx \int_{-\infty}^{\infty} dz |\psi(x, z) - \psi_0(x, z)|^2$ versus cavity detuning for patterns with odd (even) $N$. $P_{\text{odd}}$ ($P_{\text{even}}$), for $\sigma_z = 15$, $\sigma_z = 55$, $\psi_0$ is the background field. Patterns $P_1$ to $P_8$ are shown in insets (i) to (viii). A salient feature of the $U(\delta)$ branches is the tilted snaking structure: patterns with larger $N$ are stable and exist at lower $\delta$ values, while patterns with low $N$ exist at higher $\delta$ values, where instabilities typically dominate in 2D (43). The gradual shift in $\delta$ of the existence regions is a consequence of the non-uniformity of the pump, $h$, along $z$. Indeed, for uniform in $z$ pump all saddle node bifurcations, i.e., the points where $\partial_\delta U \rightarrow \infty$, are (almost) aligned in $\delta$ yielding straight snaking (45, 46). While snaking is straightforwardly expected by simple inspection of the pattern profiles (46), the tilted snaking is a rare feature (see, e.g., Ref. (43)) of central importance for this Letter, as it avoids multi-stability within a pattern family and thus enables the pattern self-replicating (erasure) phenomenon we address below (c.f. [37] section V).
Stability properties of patterns are crucial to elucidate the replication (erasure) process. Thus, all stable domains found in the $U(\delta)$ snaking diagrams [c.f. Figs. 1(b),(c)] for $\sigma_z \leq 100$ are presented in Figs. 2(a), (b) for $P_{\text{odd}}$, $P_{\text{even}}$, respectively. Stable patterns exist only in the black areas while unstable patterns exist within the light coloured areas: purple (gray) for $P_{\text{odd}}$ ($P_{\text{even}}$) (gray). Scaling: $\Delta \delta = 0.1 \Leftrightarrow 15.6$ MHz, $\sigma_x = 10 \Leftrightarrow 4.9$ mm.

The axial drift instability, crucial for comb replication, arises in our case due to the non-uniform pump field along $z$. In the uniform pump case, nonlinear states have neutral (or Goldstone) internal modes associated to displacements along $z$, universally characterised by zero growth rate. However, when the pump is modulated in $z$, the axial translational invariance is broken and the neutral’s mode eigenvalue deviates from zero to acquire a positive (negative) real part, thus leading to patterns that are unstable (stable) to drift along $z$ (see, e.g., discussions in Refs. [51]). In our case, and consistent with formal theorems for conservative systems [51], the perturbed neutral eigenvalue remains real, but oscillates around zero with $\sigma_z$, as shown in Fig. 2(c). The regions where Re($\lambda$) $> 0$ correspond to drift instabilities for $P_{\text{odd}}$ (purple) and $P_{\text{even}}$ (gray) pattern families. The amplitude of oscillations of Re($\lambda$) [plotted in log scale] decreases very fast as $\sigma_z$ increases, because the system tends to recover its axial translational invariance and drift-free dynamics. In the flat pump limit, multi-comb states become infinitely extended hexagonal patterns, whose existence and stability domain is shown in Figs. 2(a),(b).

In addition to the above stability properties, we highlight the presence of a modulation instability (MI) region, encircled in Figs. 2(a),(b) by the red line, where stable patterns $P_{1,2}$ are easily excitable by the cw pump. The simultaneous presence of MI and alternating drift instability bands for our specific choice of the pump amplitude $h_0 = 1$ is essential for the dynamical transformations between $P_{\text{odd}}$ and $P_{\text{even}}$ families, and could not be anticipated a priori. Indeed, for $h_0 > 1$ the MI region expands, but the stability domains shrink, and vice-versa for $h_0 < 1$ (not shown).

A sequence of stepwise pattern transitions of the type $P_N \rightarrow P_{N+1}$ ($P_{N-1}$) leading to deterministic self-replication (erasure) are shown in Fig. 3. Simulation of Eq. 1 was initiated with $P_2$ pattern obtained at $\delta = 0.84$, $\sigma_z = 10$, $\sigma_x = 2$, $h_0 \approx 9$. Here we take into account that in the experiment the pump profile is typically localized in $x$, hence pump amplitude, $h_0$, was adjusted to closely correspond to the dynamics observed for uniform in $x$ pump. As time goes on, the pump width, $\sigma_z$, is gradually increased up to 60, where excitation of stable $P_8$ pattern is observed, and then decreased back down to 10, leading to restoration of stable $P_2$ pattern [see Figs. 3(a) and 3(b)]. (Note that the total pump power increases with $\sigma_z$, as $h_0$ is constant). Transitions are triggered at the times [marked by red and blue dots] where varying $\sigma_z$ drives $P_N$ outside its stability region and into the region where it becomes unstable and starts to drift spontaneously upwards or downwards in $z$ [see gray (purple) shaded regions for $P_{\text{even}}$ ($P_{\text{odd}}$) families]. When $\sigma_z$ decreases (increases), the drift induces the transition $P_N \rightarrow P_{N+1}$ ($P_{N-1}$), as expected from Figs. 2(a),(b). While axially locked patterns have zero average axial position [c.f. Figs. 1(i) – (vii)], $\langle z \rangle = \int_0^{2\pi} \int_{-\infty}^{\infty} zdz|\psi - \psi_0|^2/U \equiv 0$, the $z$-drifting transient states do not, and thus the transitions $P_N \rightarrow P_{N+1}$ are characterised by pronounced peaks in $\langle z \rangle$ vs $t$, apparent in Fig. 3(b). These peaks show that transitions at larger $\sigma_z$ (larger $N$) take more time, in agreement with the fast decrease of the growth rate Re($\lambda$) with pump width [Fig. 2(c)] (see, e.g., Ref. [52] for discus-

**FIG. 2:** Existence and stability charts for (a) $P_{\text{odd}}$, (b) $P_{\text{even}}$ on the $(\delta, \sigma_z)$ plane [$h_0 = 1$, $\xi(z) = 1$]. Patterns are stable (unstable) within the black (coloured) areas. Domains for extended hexagonal pattern ($\sigma_z \rightarrow \infty$) are also shown. Red contour encloses MI area. (c) Drift eigenvalue vs $\sigma_z$ at $\delta = 0.84$ for the patterns in (a) and (b). Areas in (c) [colour matched with (a) and (b)] mark the drift bands for $P_{\text{odd}}$ (purple), $P_{\text{even}}$ (gray). Scaling: $\Delta \delta = 0.1 \Leftrightarrow 15.6$ MHz, $\sigma_x = 10 \Leftrightarrow 4.9$ mm.
and were calculated for at constant.

2 cannot be easily done, a feature that is crucial for 2 and Fig. 2. (a) and (b) are illustrated within dashed rectangle in Fig. 2. (c)=-7 free spectral ranges (FSRs). The other much weaker resonances appear due to x-localization of $\xi(x,t)$. The impact of $\xi(x,t)$, representing a non-autonomous perturbation, is well tested in 1D, but it is not in 2D. Hence, our results show the robustness of the comb replication effect in the regime where the steady state calculations of Figs. 1 and 2 cannot be easily done, a feature that is crucial for the experimental demonstration of the phenomenon. We stress that other case-specific autonomous perturbations arising from linear dispersion \[53\] and moderate Rayleigh effect \[62\] are perfectly compatible with robust nonlinear states and, for the sake of generality, are not considered here.

Figures 4(a)-(c) show multi-comb spectra in the $(k_x,z)$ plane of patterns $P_1$ (a), $P_3$ (b), and $P_8$ (c), obtained under the same conditions, as those in Fig. 3 at constant $\sigma_z$ (see labels). One-dimensional spectra at specific z values are shown in Figs 4(d)-(f). Because patterns include 7 periods in the x-direction [c.f. Figs 3(i)-(iii)], all spectra feature high-amplitude peaks separated by 7 free spectral ranges (FSRs). The other much weaker resonances appear due to x-dependence of $\xi(x,t)$, as noted previously.

average position, $(z) \neq 0$, were not found to exist within the investigated parameter space (c.f. \[37\], section V). States of this sort may exist with modulated background and, if existed, they could have frustrated comb replications.

We note that the drift instability bands in Fig. 3(a) do not coincide exactly with those in Fig. 2(c), plotted also as an inset in Fig. 3(a), for clarity. This is because patterns in Fig. 3 and Fig. 2 were calculated for unit $\xi(x,t)$ flat in x pump, while the propagation takes into account the x-localization of $\xi(x,t)$. The impact of $(x,t)$, representing a non-autonomous perturbation, is well tested in 1D, but it is not in 2D. Hence, our results show the robustness of the comb replication effect in the regime where the steady state calculations of Figs. 1 and 2 cannot be easily done, a feature that is crucial for the experimental demonstration of the phenomenon. We stress that other case-specific autonomous perturbations arising from linear dispersion \[53\] and moderate Rayleigh effect \[62\] are perfectly compatible with robust nonlinear states and, for the sake of generality, are not considered here.

Figures 4(a)-(c) show multi-comb spectra in the $(k_x,z)$ plane of patterns $P_1$ (a), $P_3$ (b), and $P_8$ (c), obtained under the same conditions, as those in Fig. 3 at constant $\sigma_z$ (see labels). One-dimensional spectra at specific z values are shown in Figs 4(d)-(f). Because patterns include 7 periods in the x-direction [c.f. Figs 3(i)-(iii)], all spectra feature high-amplitude peaks separated by 7 free spectral ranges (FSRs). The other much weaker resonances appear due to x-dependence of $\xi(x,t)$, as noted previously.
and tend to zero in the case $\xi(x, t) = 1$. In the geometry considered above, the spectra in Figs. 4(e,f) span from $1.35 - 1.82 \mu m$, corresponding to an equivalent duration of individual solitons of about $\sim 200$ fs.

In closing, we stress that the phenomenon described here reveals a mechanism that replicates and erases frequency combs along the axis of a cylindrical microresonator in a stepwise deterministic manner, affording a robust way to manipulate multi-frequency combs states in the form of spatiotemporal patterns. The frequency combs tend to be exact copies of each other and are inherently synchronised. These two features are promising for important applications such as spectroscopy, communications, RF links, and imaging. This effect is based on a fundamental drift instability that dynamically connects pattern families with odd and even number of rows (or combs), while preserving the overall symmetry. Emerging patterns via these transformations are locked and robust. Our results also bring fundamental understanding of the mechanism of pattern transformations, a phenomenon of major importance in the general context of nonlinear waves in dissipative media.

Supplemental Material: Reversible Self-Replication of Spatio-Temporal Kerr Cavity Patterns

Appendix A: Theoretical model

1. Outline for derivation

Our starting point is the wave equation for the complex electric field in a linearly dispersive and nonlinearly nondispersive dielectric (non-magnetic) environment,

\[
\nabla \times \nabla \times \mathbf{E} + \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \mathbf{E} = -\frac{1}{c^2} \frac{\partial^2}{\partial t^2} \mathbf{P}^{nl}(r, T, \mathbf{E})
\]

\[
= -\frac{\chi^{(3)}}{4\varepsilon_0^2} \frac{\partial^2}{\partial t^2} \left[ |\mathbf{E}|^2 \mathbf{E} + \mathbf{E}^2 (\mathbf{E} + \mathbf{E}^*) \right], \quad (A1)
\]

where \(*\) denotes the convolution product and \(\chi^{(3)} = \chi^{(3)}_{xx,xx} = \frac{\hbar n_0 n_2}{m^2} \) (m²/W), so intensity is \(\mathbf{E}^2\). The total permittivity is \(\varepsilon(r) = \varepsilon_c(r) + \varepsilon_e(r) - \varepsilon_{clad}\), where subscripts \(c, e, clad\) denote cavity, external coupling device, and cladding. In addition, \(\varepsilon_e = \varepsilon_re + i\varepsilon_ie\), where \(\varepsilon_re\) and \(\varepsilon_ie\) represent the real and imaginary (or lossy) parts of \(\varepsilon_e\), respectively. The total field is decomposed into many axial and polar modes of the cylinder (we assume a single radial mode only) and the one mode (or time-harmonic field) of the pump:

\[
\mathbf{E} = \int_{-\infty}^{\infty} \frac{dk_z}{2\pi} \sum_{m=0}^{\infty} A_{m,k_z}(T) \mathbf{Y}_{m,k_z}(r) e^{-i\omega_m k_z z} + p\mathbf{M}(\bar{r}) e^{-i\omega_p T}, \quad \text{pump}
\]

\[
\mathbf{Y}_{m,k_z}(r) \equiv \mathbf{F}_{m,k_z}(r) e^{i(m\beta + k_z Z)} \quad \text{intracavity}
\]

where \(\mathbf{F}(r)\) and \(\Phi(x, y)\) are the radial and transverse profiles of the cavity and driving fields, respectively. We use normalization \(\int r dr |\mathbf{F}|^2 = 1\). Modal indices are \(m \equiv \frac{\pi}{R} m_{m,k_z}/c \in \mathbb{N}\), representing the number of effective wavelengths \(\lambda_0/m_{m,k_z}\) within a microcavity roundtrip \((2\pi R)\), and \(k_z\), the axial propagation constant. Here, \(r \equiv \{r, z, \phi\}\) are the natural cylindrical coordinates for the micro-cylinder and \(f \equiv \{x, y, z\}\) describe the driving field, with \(X, Y\) being transverse to the driving field propagation direction, \(Z\) (note that \(Z\) and \(Z\) represent different coordinates, see Fig. [B.1]), \(\beta_p\) is the propagation constant of the driving field at the laser wavelength.

Substituting field in the form \(A2\) into Eq. \(A1\) and projecting onto a reference mode \(\mathbf{Y}_{m',k_z'}(r)\) leads to the rate equation for the amplitudes, \(A_{m,k_z}(T)\). Finally, introduction of the field envelope

\[
\Psi(Z, \phi, T) = \sum_{m=0}^{\infty} \int_{-\infty}^{\infty} \frac{dk_z}{2\pi} A_{m,k_z}(T) e^{-i\omega_m k_z z} + i(m-m_0)\phi + ik_z Z
\]

in the equation for \(\partial_T A_{m,k_z}\) yields the damped-driven nonlinear Schrödinger equation in physical units,

\[
\partial_T \Psi(T, \phi, Z) = -i \sum_{q=0}^{\infty} \frac{\omega^{(q,0)}}{q!} (-i\partial_\phi)^q \Psi + \frac{i}{2} \omega^{(0,2)} \partial^2 \Psi - \Gamma \Psi + i\nu |\Psi|^2 \Psi + i p\mathcal{K}(\phi, Z) e^{i\omega_p T}, \quad (A3)
\]

where bra-kets denote radial integrals within the nonlinear region. The pump distribution is given by

\[
\mathcal{K} \equiv \frac{\omega_p}{2\pi} \int_{-\infty}^{\infty} \frac{dk_z}{2\pi} \sum_{m=0}^{\infty} \mathcal{I}_V(m, k_z) e^{i(m-m_0)\phi + ik_z Z} \equiv \mathcal{F}(\mathcal{F}^*), \quad (A5)
\]

where \(\mathbf{F} = \frac{\mathbf{F}_{re} - \mathbf{F}_{im} e^{-i\phi} - ik_z Z e^{i\phi} Z}\). Finally, in-
with \( \delta' = (\omega_p - \omega_0)\tau, \quad \gamma = \Gamma\tau, \quad h' = \tau \sqrt{\tau T p K}, \) and

\[
B_{q,x} = \frac{\tau}{(2\pi R)^{q}\gamma!} \frac{\partial^q \omega}{\partial k_x^q} \bigg|_{(k_x = m_0/R, k_z = 0)}, \quad (A8)
\]

\[
B_{2,z} = \frac{\tau}{(2\pi R)^{2}\gamma!} \frac{\partial^2 \omega}{\partial k_z^2} \bigg|_{(k_x = m_0/R, k_z = 0)}. \quad (A9)
\]

Note from the above definition that \( B_1 = 1 \) because the physical group velocity, \( v_g^{ph} = \partial k_x \omega|_{(m_0/R,0)} \) is exactly \( 2\pi R/\tau \). Dispersion coefficients \( B_{2,x}, B_{2,z} \) can be eliminated by rescaling of coordinates \( x' = x' \sqrt{2B_{2,x}} \) and \( z' = z' \sqrt{2B_{2,z}} \). Also, we note that Eq. (A7) is invariant to the global scaling \( \{ t, x, z, \psi, b_{N,x}, \gamma, \delta, h \} = \{ t' a, x' \sqrt{\gamma}, z' \sqrt{\gamma}, \psi'/\sqrt{\gamma}, B_{N,x} a^{N/2-1}, \gamma/a, \delta'/a, h'a^{-3/2} \} \) \((N \in \mathbb{N} \geq 1)\). Because our system is always dissipative in practice, the scaling \( a = \gamma \) does not introduce singularities and transforms Eq. (A7) into its final dimensionless form

\[
\partial_t \psi = -i \sum_{q=2}^{\infty} \frac{b_{q,x}}{(2B_{2,x})^{q/2}} (-i \partial_x)^q \psi + \frac{i}{2} \partial_z^2 \psi + \frac{\delta \psi}{|\psi|^{2}} + ih(x, z, t), \quad (A10)
\]

which is identical to Eq. (1) from the main text with the addition of the higher dispersion terms (those with \( q \geq 3 \)) accounting for the full cylinder’s dispersion along \( x \). In main text we restricted our discussion to dispersion terms up to second order, because fixing the higher order dispersion (HOD) in a meaningful way implies selecting a particular cavity geometry (see also Appendix B), while our aim is to keep the discussion as general as possible. In addition, conversely to single pass systems, HOD (as well as other higher-order nonlinear effects) do not compromise the existence and robustness of the stationary nonlinear states, as discussed in main text.

3. A remark on normalization and MI

Physically, one motivation to work with the normalized Eq. (A10) is that when the background field is flat, \( h(x, z) = \text{const} \), the pump value \( h = 1 \) excites a nonlinear resonance with peak intensity \( \max\{|\psi|\} = 1 \), which, in turn, coincides with the modulational instability (MI) threshold for the background with anomalous GVD \( (B_{2,x} > 0) \). Thus, \( h > 1 \) means that a flat background with MI always exists (as the field modulus takes the values \(|\psi| > 1\) for some finite interval in \( \delta \)), while for \( h < 1 \) there is no MI at all (field modulus \(|\psi| < 1\) for all \( \delta \)).

The above picture changes slightly when \( h \) is a function of \( z \), as in our main text. Indeed, Figs. 2(a) and 2(b) in the main text exhibit a finite MI region around \( \sigma_z \in [2, 15] \) despite the pump amplitude \( h_0 = 1 \). The reason why the MI threshold depends upon \( \sigma_z \) at a fixed \( h_0 \) is because the diffraction term, \( \sim \partial_z^2 \psi \), must be kept when computing background states, whose amplitude then naturally depends on \( \sigma_z \). Note that we have chosen \( h_0 = 1 \) for Figs. 1 and 2 in the main text, that in the flat pump case \((h = \text{const})\) corresponds to the exact threshold for MI. This is why MI disappears in Figs. 2(a) and (b) when \( \sigma_z \rightarrow \infty \). One could have expected the MI region to close asymptotically as \( \sigma_z \rightarrow \infty \), but in reality the system is such that MI disappears at finite \( \sigma_z \) values (around 15).

\[ a. \text{ Scaling summary} \]

The relation between variables introduced in Eqs. (A10), (A7), and (A3), respectively, can be summarized in the following scaling summary:

\[
t = t' \gamma = \frac{T \gamma}{\tau}, \quad x = x' \sqrt{\frac{\gamma}{2B_{2,x}}} = \frac{X}{2\pi R} \sqrt{\frac{\gamma}{2B_{2,x}}},
\]

\[
b_{N,x} = B_{N,x} \gamma^{N/2-1} = \frac{\partial^N \omega(k_x, k_z)}{\partial k_x^N} \bigg|_{(k_x = m_0/R, k_z = 0)} \frac{\tau \gamma^{N/2-1}}{(2\pi R)^N N!},
\]

\[
\psi = \frac{\psi'}{\sqrt{\gamma}} \approx \frac{\sqrt{\gamma}}{\gamma} \Psi e^{i\omega_p T} \approx \sqrt{\frac{\gamma}{\gamma}} (F(r)|E_c(r, z, \phi, t)\rangle (r) e^{i\omega_p T - im_0 \phi},
\]

with \( \gamma = \omega_p \tau / Q \). \( \langle F|F\rangle (r) \equiv 1 \). \( E_c, V, \) and \( K \) are given in Eqs. (A2), (A4), and (A5), respectively.

\[
\delta' = \frac{(\omega_p - \omega_0)\tau}{\gamma}, \quad h' = \frac{h'}{\gamma^{3/2}} = \left(\frac{\tau}{\gamma}\right)^{3/2} \gamma^{1/2} p K,
\]

Running Maxwell solver in cylindrical coordinates

By scanning in $B_{1}$ to $A_{5}$ to $A_{11}$ that this is a reasonable assumption.

$\Phi(\bar{X}, \bar{Y}) \rightarrow \Phi(r, Z)$. In this case, Eq. [A6] becomes:

$$\mathcal{I}_V(m, k_z) = \langle \mathbf{F} \rangle \frac{\mathbf{r} - \mathbf{e}_d - \mathbf{e}_f}{2\epsilon_L} \Phi^2 e^{-i k z Z} \mathcal{I}_m, \quad (B1)$$

$$\mathcal{I}_m = \int_0^{\Delta \phi} d\phi e^{-i \beta_p (R + \Delta R) \phi} =

\begin{cases}
  \frac{i \beta_p (m - \beta_p (R + \Delta R) \Delta \phi \phi)}{m - \beta_p (R + \Delta R)}, & m = \beta_p (R + \Delta R) \\
  \frac{1}{m - \beta_p (R + \Delta R)}, & m \neq \beta_p (R + \Delta R)
\end{cases}
\quad (B2)$$

For the power estimates provided below (see Table I), we assume the simple case where the pump mode is uniform along $Z$, $\Phi(r, Z) \rightarrow \Phi(r)$. This approximation will lead to power levels which will differ from the actual values by standard form factors, depending on the particular shape of the pump beam (Gaussian, super-Gaussian or other higher-order modes of the bus waveguide). Thus results below are representative of real situations and should be taken as order of magnitude estimates.

We proceed by fixing the pump wavelength to $\lambda_p = 2\pi c / \omega_p = 1.55 \mu m$ and a reference loss parameter $\gamma = \omega_p \tau / Q = 0.001$. Then, the span $\Delta x = 32$ in our simulations (see Figs. 1 and 3 in the main text) corresponds to $\Delta X = 2\pi R$, and thus $32 = \sqrt{\gamma / 2 B_{2,x}}$ [see scaling for $x$ in Eq. (A1)] that fixes the GVD parameter to: $B_{2,x} \approx 5 \times 10^{-7}$. With the aid of a Maxwell solver, we find realistic geometries (hollow cylinders made of silica glass with radius $R$ and wall width $w$) in which such GVD is found [see Fig. B.2(a)]. Results for this geometry are shown in Table I. The process to build the table is as follows:

- Running Maxwell solver in cylindrical coordinates with fixed $R$, $w$ and $\lambda_0 = \lambda_p = 1.55 \mu m$, we get the profile $\mathbf{F}(r)$ (and normalise it to $\langle \mathbf{F} \rangle(r) = 1$), $m_0$, $\tau = 2\pi R / v_g$, and $Q$.

- By scanning in $\lambda_0$ we obtain the dispersion, $B_{2,x}(\lambda_0)$ [see Fig. B.2(a)]. Temporal duration of solitonic pulses in the patterns can be estimated using $\Delta t \approx \tau \Delta X / (2\pi R) = \tau \sqrt{2 B_{2,x} / \gamma \Delta x}$, where the full width at half maximum $\Delta x$ can be measured directly from our numerical data, see, e.g., Figs. 1 and 3 in the main text.

- $\Phi$ and $\beta_p$ are computed for another cylinder or radius $R + \Delta R$ and same wall width $w$. Note from Fig. [B.1] that this is a reasonable assumption.

- $\mathbf{F}$, $\Phi$, $\beta_p$, $R + \Delta R$ and the chosen $\Delta \phi$ are used to compute $\mathcal{I}_V$ in Eq. [B1] for a fixed $m$ and $k_z = 0$, which is inserted in Eq. [A5] to obtain the pump distribution within the cylinder, $K$. Span of values of $m$ used in the sum in Eq. [A5] is large enough to ensure convergence.

- The pump intensity $|p|^2$ is computed from $p = h_0 \gamma^{1/2} / [\tau^{3/2} V^{1/2} \max(\{K\})]$. 

**FIG. B.1:** Top view of the cylindrical microresonator and pump waveguide feeding the cavity over the arc $\Delta \phi$. The $Z$ axis corresponds to the path of the bus waveguide (in red), while $X$ and $Y$ are perpendicular to it.

**FIG. B.2:** (a) GVD for the three micro-cylinders characterised in Table II (b) Parabolic dispersion around the cylinder’s cut-off ($k_z = 0$) for the resonance $m = 549$ of the $R = 100 \mu m$ cylinder, corresponding to $\lambda_0 = 1.55 \mu m$. Profiles for the other two cylinders are almost identical.

actual trajectory of the pump, $\bar{Z}$, in relation to the $r, Z, \phi$ coordinates describing the cylindrical microresonator. In what follows, we consider the situation sketched in Fig. B.1 where the pump field propagates in the $r, \phi$ plane over a circular arc of radius $R + \Delta R$. $\Delta R$ is the radial distance between the center of the waveguides in the coupling region. Such choice of the pump geometry implies that over the coupling region, the bus waveguide has the trajectory given by $\bar{Z} = \phi(R + \Delta R)$ and the mode of the bus waveguide lies on the $\{r, Z\}$ plane, so
Finally, executing the Maxwell solver with fixed $15 \times 2$ pump powers due to the very small overlap, $\Delta x$ is meaningful provided that patterns with different number of spots behave dynamically in very similar ways. Our stability analysis suggests that this is indeed the case for patterns with $n > 3$ periods along $x$.

Finally, we note, that for a given $R$, there exist other values of wall thickness, $w \in [4, 5.3] \, \mu\text{m}$, for which the similar $B_{2,x}$ can be obtained. These values, however, are not included here, as they required unrealistically large pump powers due to the very small overlap, $T_x$, between cavity and bus modes.

**Appendix C: Pump modulation along x**

1. **About the function $\xi(x,t)$**

The function $\xi(x,t)$ was introduced in the main text to account for the realistic non-uniform in $x$ pumping conditions, in which patterns in the frame travelling with group velocity see localized pump as a pulse passing through them once per roundtrip. This pulse was assumed to be of a Gaussian shape, but it can be of any suitable form. From the scaling above, it is clear that the function (as introduced in main text)

$$\xi(x,t) \equiv \sum_{m=-\infty}^{\infty} \exp(-[x - m \Delta x - v_g t]/\sigma_x^2)$$  \hspace{1cm} (C1)

with $x \in [-\Delta x/2, +\Delta x/2]$, may be written in physical units as:

$$\xi(X,T) \equiv \sum_{m=-\infty}^{\infty} \exp(-[X - m 2\pi R - v_g^{ph} T]/\sigma_X^2),$$  \hspace{1cm} (C2)

with $X \in [-\pi R, +\pi R)$, where the physical group velocity, $v_g^{ph} \equiv \partial_{k_z} \omega(m_0/R, 0)$, is related to the normalised one in main text, $v_g$, by:

$$v_g^{ph} = v_g \frac{2\pi R}{\tau} \sqrt{\frac{2B_z x}{\gamma}}.$$  \hspace{1cm} (C3)

Mathematically, the function $\xi$ represents a periodic train of pulses spaced by $\Delta X = 2\pi R$. It can be easily seen that
In the main text we focus our attention on the interval in detuning, \( \delta \), where drift was the only existing type of instability, so that drift occurred neatly and allowed us to replicate and erase frequency combs. However, the system, as expected, is far richer than that. In particular, we show here in Fig. D.1 the role of the Hopf instability, which is the dominant instability for \( \delta \gtrsim 0.9 \). As an example, we consider here the dynamics of the single-row pattern, \( P_1 \), with 7 periods at \( \sigma_z = 55 \) and \( \delta = 1.3 \) [Fig. D.1(a)]. This pattern has both Hopf and drift instabilities with growth rates \( \sim 0.08 \) and \( \sim 0.01 \), respectively. One could expect that the Hopf instability first induces breathing and then drift causes pattern motion along \( z \). However, the strong perturbations induced by Hopf instability along propagation [Fig. D.1(c)] transform the unstable \( P_1 \) patterns into another, different \( P_1 \) pattern with 5 periods [Fig. D.1(b)]. The number of pattern periods at the output is stochastic and depends on the particular run. Once this transition into a new family happens, subsequent dynamics depends upon their stability properties. We did not attempt in this work to unveil all these details as they belong to different dynamical regimes than the one of our main focus. Such studies are thus left for future works.

Appendix D: Breathing Dynamics

2. Effect of localized pump on multi-comb spectra

In Fig. 4 of the main text showed spectra of selected spatiotemporal Kerr cavity patterns, corresponding to multi-frequency comb states. In that case, the pump field was considered localised along \( x \). Here, we show in Fig. C.1 the equivalent spectra, but with flat background along \( x \). Direct comparison between the two reveals that pump localisation along \( x \), which introduces a global envelope along \( x \), does impact the amplitude of some comb lines. In Fig. C.1 we observe some comb lines around \( k_x = 0 \), \( k_x \approx -8.8 \), at the level of \( \lesssim 100 \) dB. These lines should actually be zero for uniform in \( x \) pump, and they depart from zero only due to numerical noise. When the pump is modulated along \( x \) these lines grow substantially. As seen in Fig. 4 of the main text, these lines generally remain between \( 5 - 50 \) dB below the main comb lines, which are separated by 7 FSRs, since corresponding patterns include 7 periods along \( x \). Characteristic features and extent of two types of spectra, with modulated and uniform in \( x \) pumps, are nevertheless very similar.

Appendix E: Norm of patterns versus pump width

Figure E.1 shows the pattern branches in the norm vs pump width plane at \( \delta = 0.84 \), the value of \( \delta \) corresponding to Figs. 2(c) and Fig. 3 in the main text. The regions marked by the shaded areas in Figs. E.1(a) and (b) correspond to the drift unstable regions for \( P_{odd} \) and \( P_{even} \).
FIG. E.1: Norm, $U$, vs pump width, $\sigma_z$, of the patterns at $\delta = 0.84$ for the families with an (a) odd, $P_{\text{odd}}$, and (b) even, $P_{\text{even}}$, number of rows. Shaded areas represent the drift unstable regions, marked also in Fig. 2(c) in the main text.

These branches illustrate explicitly the fact that, at a fixed $\sigma_z$, a drift unstable states of the $P_{\text{odd}}$ family can only meet stability by reshaping themselves into the coexisting $P_{\text{even}}$ states, and vice-versa, and hence the expected pattern transitions are of the type $P_N \rightarrow P_{N\pm 1}$, depending on whether $\sigma_z$ is increased or decreased (c.f. Fig. 3 in main text). This picture, as discussed in the main text, is due to the *alternated* stability domains of the two families.

In addition, the absence of saddle node bifurcations in Figs. E.1(a) and E.1(b) makes it clear that there is no coexistence of stable and unstable $P_{\text{odd}}$ states, nor coexistence of stable and unstable $P_{\text{even}}$ states. Thus transitions within the same pattern family, e.g., transitions of the type $P_N \rightarrow P_{N\pm 2}$, cannot occur at a fixed $\sigma_z$. Such transitions could only take place if the rate at which $\sigma_z$ is varied is much higher than the rate at which drift takes place.

We emphasize that the transient states that appear dynamically during the transitions $P_N \rightarrow P_{N\pm 1}$ (c.f. Fig. 3(i)-(iii) in main text) are asymmetric (in $z$) states with a nonzero velocity along $z$. While such states may be found explicitly as stationary solutions (with drift) in the case of uniform pump $\sigma_z \rightarrow \infty$ (e.g., Rung states), they are forbidden in our case because the modulated pump (along $z$) frustrates their existence as *stationary* solutions. Thus transient states are essentially *dynamical* states and it is not clear at this point how to associate them to branches of the forms $U$ vs $\delta$ or $U$ vs $\sigma_z$.

The picture described here holds for detunings in the range around $\delta \in [0.75, 0.9]$ and $\sigma_z \gtrsim 10$ (c.f. Fig. 2 in main text). For $\delta \gtrsim 0.9$, branches start to exhibit snaking (c.f. Fig. 1(c) in main text), and thus branches analogous to those in Fig. E.1 do exhibit saddle nodes (not shown). In that case, other transitions may well occur, as those of the type $P_N \rightarrow P_{N\pm 2}$. In that region of the parameter space, however, instabilities such as Hopf (see Appendix D above) make the picture more complex as patterns do also transit into other families with different pitch along $x$.
