ABSTRACT

Solar prominences are formed by partially ionized plasma with inter-particle collision frequencies generally warranting magnetohydrodynamic treatment. In this work we explore the dynamical impacts and observable signatures of two-fluid effects in the parameter regimes when ion-neutral collisions do not fully couple the neutral and charged fluids. We perform 2.5D two-fluid (charges - neutrals) simulations of the Rayleigh-Taylor instability (RTI) at a smoothly changing interface between a solar prominence thread and the corona. The purpose of this study is to deepen our understanding of the RTI and the effects of the partial ionization on the development of RTI using nonlinear two-fluid numerical simulations. Our two-fluid model takes into account neutral viscosity, thermal conductivity, and collisional interaction between neutrals and charges: ionization-recombination, energy and momentum transfer, and frictional heating. In this paper (hereafter paper II), the sensitivity of the RTI dynamics to collisional effects for different magnetic field configurations supporting the prominence thread is explored. This is done by artificially varying, or eliminating, effects of both elastic and inelastic collisions by modifying the model equations. We find that ionization and recombination reactions between ionized and neutral fluids do not substantially impact the development of the primary RTI. However, such reactions can impact the development of secondary structures during the mixing of the cold prominence and hotter surrounding coronal material. We find that collisionality within and between ionized and neutral particle populations plays an important role in both linear and nonlinear development of RTI; ion-neutral collision frequency is the primary determining factor in development or damping of small-scale structures. We also observe that the degree and signatures of flow decoupling between ion and neutral fluids can depend on the inter-particle collisionality and on the magnetic field configuration of the prominence thread.

Key words. Sun: chromosphere – Sun: instabilities – Sun: magnetic field – Sun: numerical simulations

1. Introduction

Solar prominences consist of plasma confined in large-scale magnetic structures. The prominence plasma is usually about two orders of magnitude cooler and denser than the surrounding corona, and it is believed to have chromospheric origin (Labrosse et al. 2010). Therefore, in a prominence, plasma is only partially ionized, and the timescale associated with collisions between neutrals and ions can be comparable to hydrodynamic timescales. There have been a number of observational studies looking for indications of decoupling in velocity between ions and neutrals (Gilbert et al. 2007; Khomenko et al. 2016; Anan et al. 2017).

The Rayleigh-Taylor instability (RTI) occurs when a heavier fluid is accelerated against a lighter fluid. In a two-dimensional geometry, a small perturbation at the interface between the heavy and light fluids that varies in the direction perpendicular to the direction of the gravity may grow without bounds, depending on the scale of the perturbation. It is well known that within the ideal magnetohydrodynamics (MHD) model a discontinuous interface between heavy and light fluids is RT-unstable, and that the linear growth rate increases with increasing mode number (Chandrasekhar 1961). However, when the viscosity is taken into account the growth rate achieves a maximum for a finite value of the mode number, and falls off asymptotically to zero for higher mode numbers (Chandrasekhar 1961).

Analytical models that use more complex density profiles have also shown that the viscosity has a stabilizing effect on the linear growth rate of RTI (Bhatia 1974; Mikaelian 1993). Chen et al. (2016) showed that viscous effects also inhibit the nonlinear development of the RTI by inhibiting the secondary Kelvin-Helmholtz instability (KHI). In a laboratory plasma context, inertial confinement fusion (ICF) requires formation of a high-temperature (>10 keV) central hot spot (Weber et al. 2014; Li & Livescu 2019). Weber et al. (2014) found a turbulent kinetic energy cascade at the location of...
few theoretical studies have been performed to date. Li & Livescu (2019) studied the RTI in the ICF context and found that the extremely high heat conduction and viscosity can completely suppress the RTI development. A detailed review on the effect of the viscosity is given in Zhou et al. (2017).

The effects of the partial ionization on the development of the RTI have not been studied in detail and the results are mostly observational. Observations have shown that ionization processes might occur at the interface between the two fluids. In the observations of the RTI in the solar atmosphere the acceleration is due to gravity. Generally, in astrophysics acceleration may also have other origins, such as the pressure of the confined relativistic plasma which accelerates a “skin” of ejecta at the boundary of the Crab Nebula (Hester et al. 1996). The skin is composed of highly ionized material and, like the inner filaments present inside the nebula, is brighter, most possibly because of the higher (electron) density that could be achieved by the ionization of the neutrals (Clark et al. 1983; Hester et al. 1996).

In the solar context the RTI has been observed at the prominence corona transition region (PCTR), often at the border of prominence bubbles (Berger et al. 2017). Small-scale upflows, also called plumes, have been seen at the top border of the bubbles. It is believed that these highly dynamic columns of plasma appear due to the RTI (Berger et al. 2010; Orozco Suárez et al. 2014; Berger et al. 2017). Berger et al. (2017) observed a layer of enhanced emission situated at the edges of the bubble; as discussed below, these observations can be explained as ionization effects. The PCTR is most susceptible to partial ionization effects because of the drop in collisional frequency towards the corona.

There are only a few analytical and numerical studies of the RTI in partially ionized solar plasmas, and most of them are carried out within the single-fluid approach. These studies typically use an MHD approach where the presence of the neutrals is introduced through the ambipolar term in the generalized Ohm’s law (Árber et al. 2007; Martínez-Sykora et al. 2015; Diaz et al. 2014; Khomenko et al. 2014). In an analytical study using a single-fluid model with ambipolar diffusion, Diaz et al. (2014) find that decoupling between neutral and ionized plasma components can eliminate the stabilizing effect of the magnetic field for small scales. The cutoff imposed by the component of the magnetic field parallel to the direction of the perturbation is removed when the ambipolar diffusion is included, and the RTI growth rate increases with neutral fraction. The result has been confirmed by numerical simulations of Khomenko et al. (2014). On the other hand, in a study using a two-fluid model, Diaz et al. (2012) find that the growth rate is reduced in the presence of partial ionization effects. It is not yet fully clear what role partial ionization effects play in the development of RTI in prominences, as only a few theoretical studies have been performed to date.

This study extends the work described in Popescu Braileanu et al. (2020). One of the conclusions of Popescu Braileanu et al. (2020) is that the linear growth of the RTI can be reduced due to damping introduced by collisional effects within and between ionized and neutral particle populations. The conclusion was made after comparing linear growth rates computed from two-fluid simulations to growth rates calculated from one-fluid simulations computed semi-analytically within a single-fluid ideal MHD model. This semi-analytical model was demonstrated to show higher growth rates than the simulations on smaller scales where collisional effects play significant role in the simulations.

In this paper we systematically investigate the role of the collisional effects by turning off and on the viscosities and neutral thermal conductivity, the ionization–recombination processes, or by artificially increasing the ion-neutral elastic collision frequency within the two-fluid numerical model. We study the impact of the collisional effects on the RTI growth rate, on its nonlinear development and structure formation, and on potentially observable two-fluid properties of RTI in solar prominences such as flow decoupling between charges and neutrals.

We describe the setup and the simulations in Section 2. We study the effect of the inelastic collisions between neutrals and charges in Section 3. The effects of varying the collision frequency of elastic collisions between particles that are different (charges and neutrals) and alike (viscosity and thermal conductivity) are discussed in Section 4 where an overview is followed by a study of the RTI mode content in Section 4.1 and a detailed examination of ion-neutral flow decoupling in Section 4.2. The conclusions are drawn in Section 5.

2. Description of the problem

The simulations presented in this paper use the same 2.5D initial configuration (i.e., physical quantities that vary in two dimensions, with vector variables with three components) and governing two-fluid equations as described in Section 2 of Popescu Braileanu et al. (2020). The prominence is represented by an enhancement in the neutral density with a corresponding decrease in the temperature, which is the same for neutrals and charges in equilibrium. It is located at the center of the domain. The transition between the prominence and the coronal part of the domain is smooth, and the magnetic field can either be perpendicular to the perturbation plane or inclined and sheared over a distance \( L_x \), over which it rotates by one degree to the plane. In the simulations presented below we consider a shear length \( L_x = L_0/2 \), where \( L_0 \) is a characteristic length scale of our domain, chosen to be equal to 1 Mm. The \( L_x \) used here is smaller than the value used in the simulations presented in Popescu Braileanu et al. (2020), where \( L_x = L_0 \) was used. As discussed in Popescu Braileanu et al. (2020), shorter shear length accentuates the effects of magnetic field on RTI development, which we find to be helpful in comparing against simulations with uni-directional magnetic field background. All simulations presented here are initialized with the multimode perturbation described by Eq. 1 in Popescu Braileanu et al. (2020).
Table 1. List of the simulations. The columns, from left to right, are the short names of the simulations that appear in the text, the figures where they are referenced, and the parameters of the simulations.

Table I shows a list of all simulations presented or referenced in this paper. The following parameters are changed throughout the simulations:

- **Magnetic field configuration.** We use either the unidirectional perpendicular field configuration (simulation names that start with P) or the sheared configuration (names start with L2).
- **Inelastic collisions.** We turn off ionization–recombination effects in the governing two-fluid equations (names with the suffix -I0);
- **Elastic collisions between like particles.** We turn off the neutral viscosity and thermal conductivity terms in the governing equations, which corresponds to the limit of infinitely high collision frequency between like particles (names with the suffix -V0);
- **Elastic collisions between charged particles and neutrals.** We increase the elastic collision frequency by multiplying the value of the collisional parameter $\alpha$, calculated as in Eq. A.4 in Popescu Braileanu et al. (2019), by a factor of $10^{4}$ (names with the suffix -\(\alpha\));
- **Amplitude of the perturbation.** We vary the amplitude of the perturbation through the parameter $\delta$ in Eq. 10 in Popescu Braileanu et al. (2020) using the value $\delta = 10^{-5}$ in most of the simulations. However, for the study of the linear growth rate, we used an amplitude smaller by a factor of 100, i.e. $\delta = 10^{-4}$ (names with an additional suffix -S).

The initial equilibrium is an ideal MHD equilibrium and it assumes complete collisional coupling. After introducing it into a two-fluid code, even without a perturbation associated with the RTI, the proper equilibrium evolves due to relative drift between charges and neutrals moderated by the elastic collisional terms, and due to non-equilibrium ionization and recombination (the ionization–recombination effect can be non-negligible). In order to separate, to the first order, the evolution of the background from the evolution due to RTI, we performed simulations of the evolution of the equilibrium, indicated by the suffix “eq” in Table 1 and in the text. In all the simulations we used the...
same boundary conditions and numerical procedure as described in Popescu Braileanu et al. (2020).

The equilibrium density and temperature height profiles for charges and neutrals assumed in the simulations lead to a particular height dependence of the collisional and characteristic hydrodynamic wave frequencies. Figure 1 shows the features expressions for the ion-neutral and neutral-ion collision frequencies, and for the recombination–ionization rates and the hydrodynamic frequency, as a function of height. The expressions for the ion-neutral and neutral-ion collision frequencies, and for the recombination–ionization rates are given in Popescu Braileanu et al. (2019) (Eqs. 5, A1, A2, where we used $n_e = \rho_c/m_H$; $T_e = T_i$). The hydrodynamic frequency is estimated as $\nu_{\text{hydro}} = c_0/L_0$, where $c_0$ is the sound speed of charges and neutrals together. Another way to estimate the hydrodynamic timescale for the RTI is the characteristic Brunt-Väisälä frequency (dotted gray line). The Brunt-Väisälä frequency is calculated as $\nu_{BV} = \sqrt{g/L_d}$, where $g = 273.98$ m/s$^2$ is the gravitational acceleration and $L_d = \rho_0\frac{\partial \rho_0}{\partial z}$ is the gradient scale length of total density at $z = 0$. The two hydrodynamic timescale estimates give similar values, as shown in Figure 1.

We observe that there are regions where the timescales associated with ion-neutral interactions are larger (their frequencies are lower) or smaller (their frequencies are higher) than those of the hydrodynamic evolution. The recombination (blue solid line) evolves on a timescale that is three orders of magnitude slower than hydrodynamic evolution, and thus is unlikely to impact it. The neutral-ion collisions evolve on a much faster timescale than the hydrodynamic timescale, implying that the neutrals are closely coupled to ions by elastic collisions. On the other hand, the ion-neutral collision frequency and the ionization rate become comparable to the hydrodynamic frequency in some regions of the domain. The ion-neutral collision frequency is higher in the middle of the domain and becomes lower towards the edges (reducing the collisional coupling), while the ionization rate becomes higher at the edges. Therefore, ionization and ion-neutral coupling are expected to directly affect the hydrodynamic evolution, highlighting the need for a two-fluid model where the charges and neutrals are not assumed to be fully coupled. In contrast, any single-fluid model attempting to approximate partial ionization effects has to assume instantaneous and functionally prescribed changes to the local degree of ionization, which may omit critical nonlinear two-fluid effects (see, e.g., Leake et al. 2013; Ni et al. 2018; Ni & Lukin 2018).

3. Effect of inelastic collisions

To study the possible effects of inelastic collisions, such as electron impact ionization, on the develop-
Fig. 3. Source term from the neutral continuity equations, \( S_n \), calculated for the equilibrium atmosphere from Eq. \([1]\) as a function of height.

Fig. 4. Difference in the density of neutrals between simulations P and P-I0 at \( t = 250.7 \) s. For each simulation the density of neutrals obtained after evolving the unperturbed equilibrium has been subtracted: \( P' \equiv P - P_{eq}; \) \( (P-I0)' \equiv P-I0 - (P-I0)_{eq} \).

As discussed in Popescu Braileanu et al. (2020), the solar prominence plasma conditions modeled in this study are such that RTI damping due to finite neutral collision mean free path (MFP) begins to act on P and P-I0 in the nonlinear phase at \( t = 250.7 \) s. We observe no easily discernible difference between the two snapshots of neutral density, but there is an increased contrast in the density of charges in the P simulation compared to P-I0. The sharp edge of the structures developed in the charged fluid must be due to the ionization of the edge of the prominence thread in the hot surrounding corona.

We note that the initial background atmosphere in the simulations is not in perfect ionization–recombination equilibrium and evolves slowly. In Figure 3 we show the source term in the continuity equation of the neutral species calculated with equilibrium variables,

\[
S_n = \rho_{col}\Gamma_{rec} - \rho_{ion}\Gamma_{ion},
\]

as a function of height. We observe that this quantity is not zero everywhere, and has two minima located at \( z = -1.27 \) Mm and \( z = 2.25 \) Mm, which lead to a gradual increase in the density of charges at the edges of the prominence thread that can be observed in all simulations with ionization–recombination, in particular for simulation P in Figure 2. We also note that even in the absence of this artifact of the initial condition, due to imperfect ion-neutral coupling, the neutral density concentration associated with a weakly ionized prominence thread invariably spreads vertically due to \( \nabla p_n \) forces, and drifts downward due to gravity. Thus, it is reasonable to expect that any long-lived prominence thread may gradually evolve, in part, due to ionization at the edges of the thread.

To better illustrate the ionization–recombination effects on nonlinear evolution of RTI, Figure 4 shows the difference in the neutral density structures between the P and P-I0 simulations after subtracting the respective evolution of the unperturbed equilibrium for each simulation. We observe that the magnitude of the maximum difference between the two simulations is \( \approx 4 \times 10^{-12} \text{ kg/m}^3 \), or \( \approx 25\%-30\% \) of the peak neutral mass density values and greater than the maximum mass density of charges shown in Fig. 2. The relative excess and depletion of neutral mass density are observed to have approximately the same magnitude and are located near the main spike of falling weakly ionized material, indicating that the prominence material falls slightly faster in the simulation that neglects ionization–recombination effects. We measure the difference between the two simulations in the downward velocity of the spike at this time to be \( \approx 2-3 \text{ km/s} \), with the prominence material falling at \( \approx 12-15 \text{ km/s} \) (not shown). While it is a subtle effect this early in the formation and propagation of the spike, the difference in the evolution can be expected to grow with time leading to overestimation of the rate of the downward spike propagation in simulations that neglect ionization–recombination effects.

4. Effect of elastic collisions

As discussed in Popescu Braileanu et al. (2020), the solar prominence plasma conditions modeled in this study are such that RTI damping due to finite neutral collision mean free path (MFP) begins to act on
hand, the uni-directional magnetic field perpendicular to the plane of motion has no stabilizing effect on RTI at any scale and has little impact on the degree of decoupling between charged and neutral fluid motions. Thus, to systematically explore the impacts of elastic collisions between and within the particle species on RTI, we focus on the sheared magnetic field configuration, L2, for the former, and on the uni-directional perpendicular magnetic field configuration, P, for the latter.

We first illustrate the impact of the finite MFP between charged particles and neutrals. To do so, we compare simulations L2 and L2-\(\alpha\), run under the same conditions, the only difference being the collisional frequency between charged particles and neutrals. The L2-\(\alpha\) simulation has both \(\nu_{in}\) and \(\nu_{ni}\) increased artificially by a factor of 10^4, thus correspondingly reducing the MFP. Figure 5 shows snapshots of the neutral mass density from L2 and L2-\(\alpha\) simulations at \(t = 453\) s. It is apparent from the maps of the neutral density that a greater number of smaller scales, and density gradients that are even sharper, develop in the L2-\(\alpha\) case. Figure 6 quantifies the difference between the neutral density maps of the two simulations. We observe that the maximum differences are \(\approx 50\%\) of the peak value of the neutral density in the prominence thread. The differences appear as numerous small-scale structures, consistent with the ion-neutral decoupling impacting small-scale density structure formation during nonlinear RTI development.

We next illustrate the effects of the viscosity and neutral thermal conductivity on RTI development. To do so, we compare simulations P and P-V0, also run under the same conditions with the only difference being the lack of the viscous and heat conduction terms in the governing equations for the P-V0 simulation. Figure 7 shows snapshots of the density of neutrals
Fig. 8. Time evolution of individual horizontal mode Fourier harmonics, computed from the vertical velocity of neutrals, as a function of time. The colored lines show the Fourier amplitudes of the harmonics, grouped in sets of four, from $n = 1$ to $n = 48$ (see legend at right). The amplitudes are averaged between heights $-L_0$ and $L_0$ and within each group. The results for four simulations are shown: P (top left); P-V0 (top right); L2 (bottom left); L2-α (bottom right).

We analyzed the effect of the elastic collisions on the development of different spatial scales in the simulations. Figure 8 shows the evolution of the amplitudes of horizontal Fourier modes of the vertical velocity of neutrals for the first 48 modes. The Fourier amplitudes have been averaged in height between $-L_0$ and $L_0$, which is the region where the instability develops, and grouped and averaged in sets of four modes for better visualization (for details, see Popescu Braileanu et al. 2020).

The evolution of the RTI can be considered in two phases: in the first linear phase the amplitudes are small and modes are dominantly non-interacting; in the second nonlinear phase the mode evolution is dominated by mode-mode interactions. It is apparent that the growth rate of large-scale modes, up to $n \approx 16$, is nearly identical between the cases within each pair of simulations considered: P and P-V0, and L2 and L2-α. We also observe that the high-$n$ modes, $n \gtrsim 37$, are suppressed during the early development of the instability and do not have a linear growth phase. In the L2 simulations the growth of intermediate scales is also stabilized by the in-plane component of the magnetic field. However, in both simulations where the collisional MFP was artificially decreased, the degree of damping of high-$n$ modes is visibly smaller or altogether absent.

The growth of velocity amplitudes of the low-$n$ modes decreases at the beginning of the nonlinear phase. Through nonlinear mode-mode coupling, energy begins to be transferred to smaller scales, with the amplitude of high-$n$ modes rapidly increasing. Here, the...
the incompressible, ideal MHD assumption) is plotted as a reference (red line).

We observe in Figure 9 that for the largest scales \((n=1)\), the growth rate is the same for the four simulations, and is nearly identical to the semi-analytical calculation. The effect of the ion-neutral collisions becomes noticeable when the only simulation of the four that accounts for finite ion-neutral MFP effects \((L_2-S, \text{blue line})\) diverges from the others for \(n \gtrapprox 5\), showing lower growth rate for higher-\(n\) modes. The additional effect of viscosity is demonstrated by comparing results of the simulation with finite neutral-neutral collision MFP \((L_2-\alpha-S, \text{orange line})\), and the simulation with zeroed-out viscous and heat conduction terms \((L_2-\alpha-V0-S, \text{solid green line})\). These diverge for modes with \(n \gtrapprox 10\), confirming our previous estimate that for our atmosphere the finite ion-neutral collision MFP affects larger scales than the finite neutral-neutral collision MFP.

The main difference between the semi-analytical calculation shown in red \((L_s = L_0/2, \text{MHD,semi-an.})\) and the L2-\(\alpha-V0-S\) simulation result, namely the presence of a cutoff at \(n \approx 45\) in the simulation, should be attributed to numerical dissipation. This is confirmed by the fact that the cutoff mode number drops by a factor of almost two when the simulation resolution is decreased by a factor of two (green dotted line, labeled “L2-\(\alpha-V0-S, \text{res/2}\”). Importantly, it also implies that for all simulations analyzed elsewhere in this paper (i.e., those listed in the top and bottom portions of Table I), the cutoff due to physical effects falls at lower \(n\) than the cutoff produced by the numerical dissipation, and the modes affected by the physical dissipation can be expected to be well resolved.

Another way to quantify the effects of ion-neutral decoupling is by comparing the \(z\)-dependence of the RTI eigenmode amplitudes calculated semi-analytically in the single fluid MHD limit to the corresponding modes observed to grow in the simulations. We use vertical velocity modes for this comparison. In the semi-analytical calculation, the vertical profile of the velocity is obtained by calculating the eigenfunction \(v_z(z)\) from the second-order ordinary differential equation, Eq. (18) in Popescu Braileanu et al. (2020). In the simulations, the vertical profile of the growing modes is determined by taking a Fourier transform in the \(z\)-direction of the vertical velocities of neutrals and charges at each height at one time during the linear phase of the simulation.

Figure 10 shows the Fourier amplitudes of \(v_{1x}\) and \(v_{1z}\) modes from simulations L2-S and L2-\(\alpha-S\) compared to the semi-analytically calculated \(v_z\) eigenfunctions at heights between \(z = -0.2\) Mm and \(z = 0.2\) Mm. The Fourier amplitudes are computed from snapshots taken at the end of the linear phase at \(t = 190.4\) s. The semi-analytical eigenfunctions are normalized so that the maxima of their amplitudes coincide with those from the simulations. Functional forms for two modes, \(n = 16\) (top row) and \(n = 32\) (bottom row), are shown for the two simulations, L2-S (left column) and L2-\(\alpha-S\) (right column), are shown.

We observe that the RTI modes are narrower for higher mode numbers, as previously discussed by Popescu Braileanu et al. (2020). This property makes...
This is denoted by the prime symbol: $v' \equiv v - v_{eq}$; $P' \equiv P - P_{eq}$; $L_2' \equiv L_2 - L_{2eq}$; $P-V0' \equiv P-V0 - P_{eq}$; $L_2-\alpha' \equiv L_2-\alpha - L_{\alpha}$.

To better understand how the decoupling is related to the flow, we first show the snapshots of the velocities for the $P'$ and $L_2'$ simulations in Figure 11. The flows for the simulations where the effect of the incomplete collisional coupling is removed, $P-V0'$ and $L_2-\alpha'$, are very similar to the corresponding $P'$ and $L_2'$ simulations, and the differences cannot be seen in the flow snapshots, hence they are not shown here. In order to highlight the location of the structures, the isocontours of the neutral density are shown for the $P'$ simulations and the isocontours of the out-of-plane magnetic vector potential are shown for the $L_2'$ simulations. The peak velocity values appear to be related to the motion of the structures created by the RTI. This is especially evident in the $L_2'$ simulation, where the flow boundaries are closely aligned with the magnetic field lines.

The decoupling in velocities between charges and neutrals appears when a force that acts on only one of the two reaches the same order of magnitude as the coupling term between the two in the momentum equation. In our case the forces that act differently on the neutrals and charges are the electromagnetic forces that only act on charges, the respective pressure gradient forces on each of the species, and the viscous force which is much greater for the neutral species. Thus, we expect the decoupling to be affected by the magnetic field evolution, strong relative density gradients, and the physical viscosity.

To illustrate and quantify the different forces acting on the two species, Figure 12 shows the contributions of the pressure gradient forces, the Lorentz...
force, the viscous force for the neutrals, and the friction force due to ion-neutral collisions in the x-direction at \( z = 0 \) for the \( P' \) and \( L_2' \) snapshots shown in Fig. 11. The balance of forces is such that in both simulations the viscous force appears to make only a small contribution to the overall force balance, and the neutral pressure gradient is balanced almost exactly by the ion-neutral friction force in the momentum equation for the neutrals. In the momentum equation for the charges the pressure gradient of the charges combined with the Lorentz force are similarly balanced by the ion-neutral friction force. It should be noted that in the \( P' \) simulation the Lorentz force and the pressure gradient of charges are always in the same direction, signifying that the purely out-of-plane magnetic field is simply advected along with the ionized fluid. On the other hand, the \( L_2' \) simulation shows regions where the Lorentz force counteracts the pressure gradient of the charges, leading to more complicated force balance dynamics for simulations with an in-plane component of the magnetic field. It is also of note that the peak magnitude of the ion-neutral friction force, \( R_n \approx 2.5 \times 10^{-8} \text{ N/m}^2 \), is several times the maximum initial gravitational force experienced by the prominence thread material, \( g\rho_{\text{max}} = (273.98 \text{ m/s}^2)(1.834 \times 10^{-11} \text{ kg/m}^3) = 5.025 \times 10^{-9} \text{ N/m}^2 \).

Figure 13 shows snapshots of the decoupling in the horizontal and vertical velocities for the simulations \( P' \), \( P-V_0' \), \( L_2' \), and \( L_2-\alpha' \). This figure shows the neutral velocity differences, \( v_{zn} - v_{zc} \) and \( v_{zn} - v_{xc} \), calculated at the same time \( t \approx 202.4 \text{ s for } P' \) and \( P-V_0' \), and \( t \approx 443.5 \text{ s for } L_2' \) and \( L_2-\alpha' \). The same isocontours of neutral density and magnetic potential as in Figure 11 are plotted over the snapshots of the decoupling to facilitate the comparison. It is apparent that the decoupling is not small, reaching a few hundred m/s, and in the \( P-V_0' \) simulation that neglects neutral viscosity up to several km/s. However, as it is highly localized, the average magnitude of decoupling over the domain is significantly smaller. Snapshots of the decoupling in the sheared field \( L_2' \) simulation reveal that the decoupling is strongest in locations of greatest magnetic field tension, where the magnetic field lines are bent and compressed. By comparing this figure to Figure 11 we also find a direct correlation between the local magnitudes of the flow and flow decoupling for both simulations, \( P' \) and \( L_2' \).

The impact of the finite neutral-neutral collision MFP on the degree of flow decoupling in the nonlinear regime is demonstrated by comparing the \( P' \) and \( P-V_0' \) simulation results. We recall, as shown in Fig. 7 and Fig. 8 that the lack of viscous damping in the \( P-V_0' \) simulation results in stronger development of high-\( n \) modes, and therefore more small-scale density and flow structure in the nonlinear phase of the RTI. Comparing the top panels of Figure 13 shows that this generation of small scales also leads to significantly enhanced decoupling between the ion and neutral flows. We thus conclude that despite a small contribution to the dynamical force balance, proper accounting for the finite neutral-neutral collision MFP effects is necessary so as not to overestimate the expected flow decoupling as a result of nonlinear small-scale formation.

As expected, the ion-neutral flow decoupling in the \( L_2-\alpha' \) simulation with a near-zero ion-neutral collision MFP (Fig. 13 bottom right) is five orders of magnitude smaller than the \( L_2' \) case (bottom left). This once again emphasizes the importance of accurately capturing the finite ion-neutral MFP effects. Another way to statistically quantify the magnitude of RTI flows and ion-neutral flow decoupling is via bivariate probability density functions between the velocities (x-axis) and the decoupling in the velocities (y-axis) within the simulation domain. The left panels of Figure 14 show the bivariate probability density functions between the horizontal velocity and the decoupling in the horizontal velocity for the \( P' \) (top panel) and \( L_2' \) (bottom panel). The right panels of Fig. 14 show the same for the vertical velocities. These bidimensional histograms were obtained over the last 50 sec of each simulation: for time intervals \( t = \{393, 443\} \text{ s for } L_2' \) and \( t = \{200, 250\} \text{ s for } P' \), with the data taken over
5. Conclusions and discussion

In this article we explored the development of the Rayleigh-Taylor instability by focusing on the effects of elastic and inelastic collisions between and within neutral and charged particle populations in the context of a two-fluid model. We studied how the linear and nonlinear stages of the instability depend on the collisional MFP parameters, on their influence on the RTI mode growth rates, and on the decoupling between neutrals and charges. The conclusions of this work can be summarized as follows:

- The action of inelastic processes of ionization–recombination leads to the formation of high-density structures within the ionized fluid that forms at the interface between the cold prominence and the hot coronal material. These structures follow the evolution of the RTI eddies, and are due to the ionization of the neutrals at the interface. The RTI linear growth rate is not affected by inelastic collisions.

- The effects of finite elastic collision MFP for both ion-neutral and neutral-neutral collisions (e.g., viscosity) suppress the RTI linear growth rate on small scales. Ion-neutral collisions qualitatively modify the structure of RTI modes for high mode numbers; the effect of viscosity appears at yet smaller scales.

- During nonlinear RTI development, non-negligible decoupling between velocity fields of neutrals and...
Fig. 13. Snapshots of the decoupling in horizontal and vertical velocities. Top left: P'; top right: P-V0'; bottom left: L2'; bottom right: L2-\alpha', where the evolution of the background has been removed. The snapshots in the top row are shown at time \( \approx 202 \) s, and those in the bottom row at time \( \approx 443 \) s. The isocontours of the neutral density spanning the range from the minimum to the maximum value are plotted for the snapshots of \( P' \) and P-V0' simulations (top). The magnetic field lines are plotted over the L2' and L2-\alpha' snapshots as isocontours of the magnetic potential (bottom), with levels corresponding to values from \( 0.6A_y^{\text{max}} \) and \( A_y^{\text{max}} \), where \( A_y^{\text{max}} \) is the maximum value of \( |A_y| \).

charges, at a few hundred m/s, is observed at locations of strong gradients in neutral density and/or magnetic field. This localized decoupling is due to the differential between the MHD forces acting separately on charges and neutrals becoming comparable to the collisional ion-neutral coupling force. The decoupling is more pronounced on small spatial scales.

- Statistical analyses of the simulation results using histograms of the flow map demonstrate up-down asymmetry in both flow and flow decoupling, in particular in simulations with a sheared magnetic field configuration. Furthermore, while vertical flow is generally stronger than horizontal flow, the ion-neutral flow decoupling is more pronounced in the horizontal direction for both magnetic field configurations. These statistical features can potentially be detectable in observations.

As noted above, as a consequence of non-equilibrium ionization, we observe that the RTI instability leads to the formation of a relatively thin high-density layer of ionized fluid surrounding the falling cold high-density neutral prominence material. This non-equilibrium ionization (and excitation) process is one possible explanation for the enhanced emission detected at the prominence corona transition region at the edges of the bubble in observations by Berger et al. (2017). The excessive brightness of the layer of highlyionized material seen at the boundary of the Crab Nebula (Clark et al. 1983; Hester et al. 1996) could similarly be explained by a higher electron density than otherwise expected.

A two-fluid model allows the quantification of the degree of coupling between ions and neutrals. We found large values of the decoupling in velocity, which might be related to the magnetic activity being localized at the places where the magnetic field is significantly stressed. As the decoupling is highly localized, it is difficult to measure it directly from observations. Direct measurements of the magnetic fields in coronal structures are similarly challenging. However, statistical information about the decoupling, such as histograms, could be compared between the theoretical estimations and the observations to infer information about both plasma flow and local magnetic field structure.
Fig. 14. Bivariate probability density functions between the velocity ($x$-axis) and the decoupling in the velocity ($y$-axis) for the $P'$ case (top panels) and $L2'$ case (bottom panels), where the evolution of the background has been removed. In both cases, all velocity values over the last 50 sec of each simulation, and at the vertical location between $-2L_0$ and $2L_0$ have been considered. Left panels: Bivariate probability density functions corresponding to horizontal velocity; Right panels: Same, but for the vertical velocity. The vertical dotted line gives the location of zero velocity value.

Díaz et al. (2012) studied analytically the instability in a two-fluid approach where they consider a three-dimensional setup with two uniform regions separated by an interface, and a uniform magnetic field everywhere. They find a much lower growth rate in the two-fluid approach compared to the single-fluid approach, the reason for the decrease being that the ion-neutral interactions are not taken into account in the MHD approximation. Our result is similar to that of Díaz et al. (2012) in that the collisional interaction between neutrals and charges decreases the growth rate.

Khomenko et al. (2014) performed a high-resolution numerical study of the RTI in a much more idealized setup. Similar to several studies of magnetic flux emergence through the solar photosphere (e.g., Amber et al. 2007 and Nóbrega-Siverio et al. 2020), they modeled partial ionization effects within a single-fluid approach via the ambipolar diffusion term. In agreement with the analytical study of Díaz et al. (2014), Khomenko et al. (2014) found an increase of about 50% in the growth rate on small scales in the simulations that included the ambipolar term compared to pure MHD simulations. The increase in the RTI growth rate was observed on scales where in the single-fluid approximation the in-plane component of the magnetic field imposes a cutoff. When partial ionization effects are taken into account, it was shown that the cutoff is removed, allowing for a small but non-negligible linear growth rate on small scales beyond the MHD cutoff. While this might appear to contradict the conclusions of the present work, there is a critical difference between the two in the choice of the RTI-unstable equilibrium. This key difference is the more realistic smoothly varying interface between the cold dense prominence and the hot low-density coronal material considered here. Another source of the difference between the results of Khomenko et al. (2014) and the present work is that the MHD model with ambipolar diffusivity assumes more coupling between ions and neutrals than a fully two-fluid model and may capture their interaction in a different manner.
