The spin-orbit coupling plays an important role in the spin Hall effect and the topological insulators. In addition, the spin-orbit coupled Bose-Einstein condensates show remarkable quantum many-body phase transition. In this work we tune the exciton polariton condensate by virtue of the Rashba-Dresselhaus (RD) spin-orbit coupling in a liquid-crystal filled microcavity where perovskite CsPbBr$_3$ microplates act as the gain material at room temperature. We realize an artificial gauge field on the CsPbBr$_3$ exciton polariton condensate, which splits the condensates with opposite spins in both momentum and real spaces. Our work paves the way to manipulate the exciton polariton condensate with a synthetic gauge field based on the RD spin-orbit coupling at room temperature.

The spin-orbit coupling describes the interaction between the spin and orbital degrees of freedom of a particle. It leads to plethora of physical phenomena such as the spin Hall effect and topological insulators. Dresselhaus and Rashba proposed electron’s spin-orbit coupling in noncentrosymmetric zinc-blende or wurtzite semiconductors. The engineering of the spin-orbit coupling in solids is usually limited by the growth or fabrication process of the materials like high quality semiconductors. Thus an adjustable platform, where the spin-orbit coupling like the Rashba or Dresselhaus coefficient can be precisely manipulated, is highly expected. Recently, the cold atom condensate offers to tune the spin-orbit coupling precisely using lasers to engineer the fine structures of the states of the system. For example, in the Bose-Einstein condensation (BEC) of cold atoms, the spin-orbit coupling provides opportunities to investigate the quantum many-body phase transition from a spatially spin-mixed state to a phase-separated state by utilizing Raman lasers. A stripe phase with supersolid properties is also revealed in the cold atom condensate. However, the ultra-low temperature needed to realize the BEC of the cold atoms limits the application and fundamental investigation of the spin-orbit coupling on the bosonic condensate.

Exciton polaritons, which form due to the strong coupling between excitons in quantum wells and cavity photons in a microcavity, can experience similar condensation process as the cold atoms. Being a composite boson with small effective mass, an exciton polariton can condense at much higher temperature or even up to room temperature, so it can provide an alternative to the cold atom to study the spin-orbit coupling on bosonic condensation without complicated laser cooling technique. In addition, exciton polaritons can inherit the spin-orbit coupling of light in view of the cavity photon component that can be manipulated by the detuning of the microcavity. The spin-orbit coupling of light results in the quantum spin Hall effect of light, and a non-cyclic optical geometric phase in a rolling-up microcavity. Especially in a liquid crystal (LC) filled microcavity, a synthetic spin-orbit interaction, which is similar to the RD Hamiltonian based on the Fabry-Perot microcavity, has been realized at room temperature. The key point in that work is that a voltage can control the orientation of the long axis of the LC molecule, which leads to anisotropic refractive index modulation of the cavity layer.

By choosing a semiconductor with robust excitons which can strongly couple with the cavity mode with tunable RD coefficients, exciton polaritons offer to investigate the spin-orbit coupling induced phase transition in a bosonic condensate with adjustable manner at room temperature. Among the materials that can sustain exciton polariton condensates at room temperature, perovskite CsPbBr$_3$ has attracted intensive attention due to the supreme photonic properties. Inserted into a microcavity, CsPbBr$_3$ offers an excellent platform to investigate the strong and novel light-matter interaction, such as exciton polariton condensation in a waveguide or a lattice at room temperature. Although Rashba Hamiltonian has been realized in a bare organic-inorganic perovskite, the effects of RD spin-orbit coupling on the exciton polariton condensate based on perovskite at room temperature are not explored yet.

In this work we demonstrate the RD effect on the exciton polariton condensate based on CsPbBr$_3$ microplates in a LC filled microcavity. The LC microcavity offers an excellent platform to investigate the strong and novel light-matter interaction, such as exciton polariton condensation in a waveguide or a lattice at room temperature. Although Rashba Hamiltonian has been realized in a bare organic-inorganic perovskite, the effects of RD spin-orbit coupling on the exciton polariton condensate based on perovskite at room temperature are not explored yet.

offers to tune the RD coefficients and realize a synthetic gauge field by applying the voltage across the microcavity. We insert CsPbBr$_3$ microplates into the cavity layer and demonstrate the exciton polariton condensation at room temperature. The applied voltage across the microcavity tunes the RD coefficients onto the exciton polariton condensate, acting as a synthetic gauge field and splitting the exciton polaritons with opposite spins in real space and momentum space. More importantly, we realize the manipulation of the polariton condensate by the external voltage. Our work paves the way to realize topological photonics based on the exciton polariton condensate at room temperature.

In the LC microcavity where CsPbBr$_3$ microplates are inserted, on the one hand, cavity photons can strongly couple with excitons in the CsPbBr$_3$ layer. On the other hand, cavity photon modes can be tuned by electrically controlling the crystal molecule’s orientation, giving rise to the RD effect. When the two effects occur simultaneously in this system, the system’s Hamiltonian ($4 \times 4$) in the exciton-photon linearly polarized H-V basis reads

$$H(k) = \begin{bmatrix}
E_x & 0 & \Omega & 0 \\
0 & E_x & 0 & \Omega \\
\Omega & 0 & E^H_c + \frac{\hbar^2 k^2}{2m} + \xi k_x & \beta_0 + \beta_1 k^2 e^{2i\varphi} \\
0 & \beta_0 + \beta_1 k^2 e^{-2i\varphi} & E^V_c + \frac{\hbar^2 k^2}{2m} - \xi k_x & \Omega
\end{bmatrix}.$$  

(1)

Here, $E_x$ is the exciton energy and for different spins they are the same. $E^H_c$ and $E^V_c$ are the ground energies of cavity photon modes with orthogonal polarization and effective mass $m$. Here, we assume that the two cavity modes are near resonant and have the same effective mass. The two cavity photon modes are perpendicularly linearly polarized and have different parity. The former leads to that they can strongly couple only to their corresponding excitons with the coupling strength $\Omega$ and the latter results in the RD effect with the spin-splitting strength $\xi$ along $k_x$ direction. $\beta_1$ denotes the XY splitting. $\beta_1$ represents the TE-TM splitting and $\varphi \in [0, 2\pi]$ is the polar angle. The composited polaritons inherit the RD interaction from the cavity photon component. The LC molecule can be rotated by the external voltage, which modulates the anisotropic refractive index distribution within the microcavity. The changes of the refractive indices alter only one of the perpendicularly polarized cavity photon modes, such that two LP branches can approach each other and consequently are shifted along $k_x$ direction depending on the polarization when they are brought into resonance.

Firstly, we design the microcavity by calculating both the reflectivity and the electric field distribution of the microcavity using the transfer matrix method (the simulation results are shown in Fig. S1). The strong exciton-photon coupling can be realized thanks to the giant binding energy and oscillator strength of the excitons in the CsPbBr$_3$ microplate which is placed at the local maximal electric field position of the microcavity (c.f. Fig. S1). In the experiments, the CsPbBr$_3$ microplate was grown by the CVD method (the details can be found in the Methods section), and then it was transferred onto the bottom DBR with the center wavelength of the stop band at 530 nm. The microcavity was fabricated by pasting the top DBR afterwards using adhesive. Finally, the LC is filled into the empty cavity layer to form the microcavity (the details of the microcavity can be found in the Methods section).
section). The schematics of the whole structure of the sample is illustrated in Fig. 1.

We measure the dispersion of the microcavity under the voltage of 2 V by a home-made momentum-space spectroscopy (see Fig. S2 in the SM). The excitation source is a femtosecond laser with the wavelength of around 400 nm and spot size of around 45 μm. The size of the CsPbBr$_3$ microplate we chose in the experiments is around 10 μm, which can be covered by the pumping laser spot. The photoluminescence dispersion of the microcavity below the threshold is shown in Fig. 2(a), where several sets of modes are observed below the exciton resonance at 2.406 eV. Each set of the modes contains two lower-polariton (LP) branches due to the anisotropy of the microcavity induced by the LC cavity layer. Due to the finite size of of the CsPbBr$_3$ microplate, the dispersion become discrete at larger momenta. The appearance of the multiple sets of polaritons are due to the microcavity which sustains multiple cavity photon modes that can strongly couple with the near resonant excitons. The dispersion curvature of the LP branches is reduced when the detuning between the cavity photon modes and the exciton resonance of the CsPbBr$_3$ microplate is smaller. We note that similar multiple polariton branches are also observed in a bare perovskite crystal [25].

Within each set of modes in Fig. 2(a), the polarization of the two LP branches are perpendicular to each other: One is vertically linearly polarized and the other one is horizontally linearly polarized, which are shown in Fig. 3(a-c) and confirm the existence of the XY splitting due to the anisotropy of the microcavity. We note that the anisotropy of the CsPbBr$_3$ microplate itself can be neglected due to the very small thickness of around 200 nm. The anisotropic refractive index of the CsPbBr$_3$ microplate can be engineered in combination with the anisotropy of the LC to open an energy gap with a non-zero local Berry curvature [26] in the future work. We also note that there exist some dispersion with much larger curvatures, which come from the area out of the CsPbBr$_3$ microplate [27] and do not affect the main results in the current experiments. The dispersion with small curvatures are fitted by coupled oscillator models as shown in the SM and one can estimate the Rabi splitting of the polaritons within the microcavity to be around 45 meV. The exciton or cavity photon fraction of the multiple-branch polaritons can be obtained by calculating the Hopfield coefficients which are plotted in Fig. S2 in the SM. It shows that the cavity photon components in the LP$_3$ and LP$_4$ are much larger than those in the LP$_1$ and LP$_2$ branches due to the increased detuning of the former.

Increasing the laser power to around 40 μW leads to the condensation of exciton polaritons, which can be seen in Fig. 2(b). The polaritons macroscopically occupy the ground state of the lower branch LP$_4$, with the superlinear increase of the integrated intensity against the pump-
produced greatly, so that polaritons condensed to only one branch. In this case, the external voltage acts to manipulate the polariton condensate, which is very challenging to be realized in common microcavities.

In the experiments, the polaritons condense at $k_x = 0$, such that we observe the condensate mainly located at the center of the Brillouin zone when the voltage is zero. The spin-dependent momentum space imaging can be seen in Fig. 4 where the spin-splitting of the polariton condensate is absent when the voltage is zero (Fig. 4(a-c)), whereas the polariton condensate is split at 4.5 V as shown in Fig. 4(d-f). In this scenario, the momentum of the polariton condensate is shifted and different spin components gain a non-zero momentum of around $k_x = 0.258 \mu m^{-1}$. In accordance with the momentum space, the RD interaction in the microcavity also modifies the distribution of the polariton condensate in real space. In the cold atom condensate, the two Raman lasers induce the coupling of the inner states of the atoms and create the Rashba interaction, which results in the separation of the atoms with different spins. In the experiments, we measure the distribution of the exciton polariton condensate in different spin polarizations and observe the spin-splitting of the polariton condensate in real space (see Fig. 4(j-l)) by around 0.86 $\mu m$. This spin-splitting of the polariton condensate in real space is also absent when the voltage across the microcavity is zero (Fig. 4(g-i)), demonstrating the RD effect occurring at 4.5 V. These results show clearly the RD effect onto the exciton polariton condensates at room temperature.

To summarize, in this work we use the LC filled microcavity to investigate the spin resolved distribution of the polariton condensate in the real space and momentum space at room temperature. The RD effect originated from the anisotropy of the LC microcavity modifies the energy bands of the microcavity and splits the polariton condensate in both real and momentum space. Our work offers to study the synthetic gauge field and nontrivial band structure based on the polariton condensate in CsPbBr$_3$ microcavity at room temperature.
