Data-driven and constrained optimization of semi-local exchange and non-local correlation functionals for materials and surface chemistry

Kai Trepte1,* and Johannes Voss1,b

SUNCAT Center for Interface Science and Catalysis, SLAC National Accelerator Laboratory
Menlo Park, CA 94025, USA

Reliable predictions of surface chemical reaction energetics require an accurate description of both chemisorption and physisorption. Here, we present an empirical approach to simultaneously optimize semi-local exchange and non-local correlation of a density functional approximation to improve these energetics. Through a combination of reference data for solid bulk, surface, and gas-phase chemistry and physical exchange-correlation model constraints, this approach leads to the VCML-rVV10 exchange-correlation functional. Owing to the variety of training data, the applicability of VCML-rVV10 extends beyond surface chemistry simulations, with optimized gas phase reaction energetics and accurate description of bulk lattice constants and elastic properties.

I. INTRODUCTION

Kohn-Sham (KS) density functional theory (DFT)1,2 is one of the most widely used electronic structure theories, providing reasonable accuracy for many physical properties of atoms, molecules, surfaces, and solids.3 The approximations to electronic exchange and correlation (XC) enabling the practical use of KS DFT, the so-called XC functionals, have been developed for decades4,5 resulting in a variety of both empirical6–9 and non-empirical10–13 functionals. In the latter approaches it was established that fulfilling analytical constraints14 leads to functionals with improved predictions of molecular and bulk properties.12,15,16 Typically, empirical as well as non-empirical functionals describe some physical and chemical properties such as bulk lattice structure or reaction energies with improved accuracy at the price of worse prediction of other properties.

To obtain an XC functional that describes a wide range of physical properties accurately, strategies from the empirical and non-empirical XC functional development approaches can be combined. Constraints from the latter can be imposed while fitting a multi-parameter empirical XC functional form to experimental and quantum chemistry reference data.

There are several approaches combining constraints and data for XC functionals.12,19 Recently, our group has applied such a combined approach to construct a multi-purpose, constrained and machine learned (MCML) XC functional that shows improved predictions of surface and gas phase reactions without sacrificing the good description of bulk properties via previous approaches.17 The MCML functional is a so-called semi-local functional, lacking an explicit description of non-local, i.e., van der Waals (vdW) type correlation. Supplementing a semi-local functional with vdW correlation does not only affect the performance for vdW-dominated interaction energies, but the attractive dispersion forces can lead to even stronger overbinding in chemisorption systems than already present in some semi-local approximations.20 In existing approaches, typically either the semi-local part of the functional is optimized to compensate for effects of overbinding or lattice spacing contraction from the attractive vdW terms,21,22 or the vdW part is optimized using, e.g., the parameterized, semi-empirical rVV10 non-local vdW term23–25 to optimize performance on dispersion-dominated benchmark data in combination with a fixed underlying semi-local functional.

FIG. 1. Basic outline of the VCML-rVV10 optimization.
In the present work, we optimize the semi-local exchange and non-local correlation parts of a vdW XC functional simultaneously for several bulk, surface, and gas phase property predictions. This simultaneous optimization of the semi-local exchange functional form and an rVV10 non-local term enables us to construct a functional that is accurate for a range of materials properties governed by different types of chemical bonds, without having to compromise the accuracy for the description of ionic, covalent and metallic bonds for dispersive interactions, or vice versa. Incorporating physical constraints into this empirical approach leads to the VCML-rVV10 functional (vdW functional using constraints and machine learning, employing the rVV10 formalism), see Fig. 1. This name shall clearly separate our functional from MCML, as the semi-local exchange functional parts of MCML and VCML(-rVV10) are different, the latter not simply being a vdW-supplemented form of MCML. While we optimize the semi-local exchange as well as the non-local correlation part of our functional, for semi-local correlation we employ REGTPSS.

This article is structured as follows. In Section II, a brief introduction of the theoretical background including the rVV10 formalism is given. The used computational parameters are shown in Section III, after which our functional optimization approach is presented in Section IV. All employed data sets are described in Section V, followed by the main results in Section VI. A conclusion is presented in Section VII.

II. THEORETICAL BACKGROUND

Atomic units are being used throughout this section. In the KS formulation of DFT, the total energy of a system with total electron density \( n(\mathbf{r}) = n^\uparrow(\mathbf{r}) + n^\downarrow(\mathbf{r}) \) can be expressed as

\[
E_{\text{KS}} = T[\mathbf{n}^\uparrow, \mathbf{n}^\downarrow] + E_{\text{ext}}[\mathbf{n}] + E_{\text{H}}[\mathbf{n}] + E_{\text{XC}}[\mathbf{n}^\uparrow, \mathbf{n}^\downarrow].
\]

Here, \( T \) is the non-interacting kinetic energy, \( E_{\text{ext}} \) is the energy of the interaction with an external potential, \( E_{\text{H}} \) is the Hartree energy of the electrons, and \( n^\uparrow \) and \( n^\downarrow \) are the spin densities of a system with collinear spins. Exchange and correlation effects are treated via the exchange-correlation functional \( E_{\text{XC}} \).

The electron density is the fundamental building block of DFT, and the optimal density will give the optimal energy as well as any other property. While DFT is in principle exact, the \( E_{\text{XC}} \) needs to be approximated. Such approximations range from the local (spin) density approximation (LSDA), where only the density itself is taken as a parameter, to generalized gradient approximations (GGAs), which include the gradient of the density, to meta-GGAs which also include a dependence on the kinetic energy density of the occupied orbitals. The order of such approximations can be summarized via their ingredients in a so-called Jacob’s ladder of DFT.

The exchange energy for meta-GGAs is defined as an integral of the exchange energy density per electron of the homogeneous electron gas (HEG) at density \( n(\mathbf{r}) \), \( E_{\text{HEG}}[\mathbf{n}(\mathbf{r})] = -\frac{1}{4} (3/\pi)^{1/3} n(\mathbf{r})^{1/3} \), multiplied by an exchange enhancement factor \( F_X \)

\[
E_X[n(\mathbf{r})] = \int d^3 r n(\mathbf{r}) E_{\text{HEG}}[\mathbf{n}(\mathbf{r})] F_X(s(\mathbf{r}), \alpha(\mathbf{r}))
\]

where

\[
s(\mathbf{r}) = \frac{|\nabla n(\mathbf{r})|}{2 k_F(\mathbf{r}) n(\mathbf{r})}
\]

is the reduced density gradient with \( k_F(\mathbf{r}) = \sqrt{3\pi^2 n(\mathbf{r})} \) being the Fermi wave vector. The dependence on the kinetic energy density can be described as

\[
\alpha(\mathbf{r}) = \frac{\tau_{\text{KS}}(\mathbf{r}) - \tau_{\text{Weizs"acker}}(\mathbf{r})}{\tau_{\text{HEG}}(\mathbf{r})},
\]

with \( \tau_{\text{KS}}(\mathbf{r}) = \frac{1}{2} \sum_i f_i \langle \nabla \phi_i(\mathbf{r}) \rangle^2 \) being the kinetic energy density based on the KS orbitals \( \phi_i(\mathbf{r}) \) with occupation \( f_i \), \( \tau_{\text{Weizs"acker}}(\mathbf{r}) = |\nabla n(\mathbf{r})|/8n(\mathbf{r}) \) being the von Weizs"acker kinetic energy density describing the single orbital limit, and \( \tau_{\text{HEG}}(\mathbf{r}) = \frac{3}{2} (3\pi^2)^{2/3} n(\mathbf{r})^{5/3} \) is the non-interacting kinetic energy density of a HEG at density \( n(\mathbf{r}) \). The term \( \tau_{\text{Weizs"acker}}(\mathbf{r}) \) vanishes for zero charge density gradient and equals \( \tau_{\text{KS}}(\mathbf{r}) \) for a single orbital density. Accordingly, Eq. 4 approaches zero in the single orbital limit and one in the homogeneous limit where \( \nabla n(\mathbf{r}) = 0 \) and \( \tau_{\text{KS}}(\mathbf{r}) = \tau_{\text{HEG}}(\mathbf{r}) \). With that, the parameter \( \alpha \) can characterize the type of bonding in a system.

For spin-polarized systems, \( E_X \) is obtained via the spin scaling relation

\[
E_X[n^\uparrow(\mathbf{r}), n^\downarrow(\mathbf{r})] = \frac{E_X[2n^\uparrow(\mathbf{r})] + E_X[2n^\downarrow(\mathbf{r})]}{2}.
\]

The exchange-enhancement factor \( F_X \) is optimized in this work by training against reference data (see Section IV for more details).

In the rVV10\textsuperscript{20,22} methodology, a non-local correlation energy is introduced as

\[
E_{\text{c,nl}} = \frac{1}{2} \int d^3 r d^3 r' n(\mathbf{r}) \Theta(n(\mathbf{r}), n(\mathbf{r}')) n(\mathbf{r}').
\]

The non-local kernel as described by Sabatini et al.\textsuperscript{23} is given by
\[ \Theta(n(r), n'(r'))^{\text{VVK10}} = -\frac{3}{2} \frac{1}{(q(r)R^2 + 1)(q'(r')R^2 + 1)(q(r)R^2 + q'(r')R^2 + 2)}, \]

in which
\[ q(r) = \omega_0 \frac{n(r)}{k(r)} \]

and \( R = |r - r'|. \) The same expression is obtained for \( q' \) by replacing \( r \) with \( r' \). The term \( \omega_0 \) depends on the local band gap as well as the plasma frequency, see Sabatini et al.\(^{24}\) as well as the supporting information (SI), Sec. 1. Importantly for further discussion, the term
\[ k(r) = 3\pi b \left( \frac{n(r)}{9\pi} \right)^{\frac{1}{3}} \]
determines the short-range damping of the \( R^{-6} \) divergence of the non-local kernel. The parameter \( b \) needs to be optimized for any functional \( E_{\text{XC}} \) that \( E_{\text{cml}} \) is added to. Simply speaking, the larger the \( b \) parameter, the weaker the vdW interaction. The optimization of this parameter is discussed in Section IV. For additional details we refer to the original works of Vydrov and Van Voorhis\(^{23}\) and Sabatini et al.\(^{24}\)

### III. COMPUTATIONAL DETAILS

In this work, the Vienna ab initio Simulation Package (VASP\(^{28}\)) was employed. The DFT calculations were carried out using projector-augmented wave\(^{29}\) pseudopotentials\(^{30}\) which are based on PBE\(^{10}\) all-electron atomic calculations, and a plane wave basis set. An energy cutoff of 1000 eV (73.50 Ry or 36.75 \( E_b \)) was used together with an electronic SCF tolerance of \( 10^{-7} \) eV. For geometry optimizations, forces were converged such that the maximum force per atom is at most \( 10^{-2} \) eV/Å (in the ADS41 set (see SI, Tab. ST25), \{H\_2O,CH\_3OH\}@Pt111 using SCAN\(^{12}\) and \{H\_2O,CH\_3OH,CH\_3,H\_2CH\_2\}_@Pt111 using SCAN-rVVK\(^{10}\)) required an increased criterion of \( 2 \cdot 10^{-2} \) eV/Å because of numerical instabilities, which are absent in r\(^2\)SCAN\(^{11}\)). The k-point spacing for the surface (in 2 dimensions) and bulk (in 3 dimensions) calculations was at most 0.018 Å\(^{-1}\). A Gaussian smearing of KS occupation numbers with a width of \( 2 \cdot 10^{-2} \) eV was used for surfaces and bulk systems.

For data sets involving molecules, the unit cell has been prepared as follows. Around the largest system in the set, a box was constructed such that there is at least 20 Å in between periodic images in all directions. This box was employed for all molecules in the corresponding data set. For atoms, a cell of 23 Å was used.

To compare the performance of the VCML-rVVK functional, calculations were also performed with PBE\(^{10}\), MS2\(^{31}\), SCAN\(^{12}\), r\(^2\)SCAN\(^{13}\) (a regularized modification of SCAN with better numerical stability), SCAN-rVVK\(^{10}\), MCML\(^{14}\), and MCML-rVVK\(^{10}\) (introduced in this work). For the error analysis, the mean error (ME) and mean absolute error (MAE) are computed
\[ \text{ME} = \frac{1}{N} \sum_{i=1}^{N} x_i^{\text{calc}} - x_i^{\text{ref}} \]
\[ \text{MAE} = \frac{1}{N} \sum_{i=1}^{N} |x_i^{\text{calc}} - x_i^{\text{ref}}|, \]

where \( x_i^{\text{calc}} \) is the calculated value and \( x_i^{\text{ref}} \) the corresponding reference value. These values are provided in the SI, Tab. ST7, 9, 11-19, 21-24 and 26. All individual errors for any system of a data set are computed by \( x_i^{\text{calc}} - x_i^{\text{ref}} \).

### IV. FUNCTIONAL FITTING APPROACH

#### A. General outline

In the following, the meta-GGA as well as the vdW fitting procedure is presented. The procedure to obtain the meta-GGA functional form has been outlined in Brown et al.\(^{17}\) for the MCML functional. We will briefly discuss its main components here. Our exchange enhancement factor is expanded in a series of Legendre polynomials
\[ F_X(s(r), \alpha(r)) = \sum_{i=0}^{7} \sum_{j=0}^{7} c_{ij} P_i(\hat{s}(r)) P_j(\hat{\alpha}(r)), \]

where
\[ \hat{s}(r) = \frac{2s(r)^2}{\eta + s(r)^2} - 1 \]

maps the semi-infinite interval of reduced density gradients \( s \) to the interval spanned by the Legendre polynomials, \([-1,1]\). Here, \( \eta = \kappa/\mu_{\text{GE}} \) is used to represent the exchange enhancement of PBE\(^{32}\) by the first two Legendre polynomials \( P_0(\hat{s}(r)) \) and
The spurious Hartree energy in the H atom for s expansion for $F_i$, i.e., applied to our functional, an optimal semi-local meta-GGA functional. The Eq. (12), as described in the next sections, delivers s The transformations of $SI$, Fig. SF1. Optimizing the 64 coefficients $c_{ij}$ with a curvature of 2 $\mu$Hartree energy for the hydrogen atom of order coefficient of the gradient correction to the free electron gas exchange energy. Similarly,

$$\alpha(r) = \frac{(1 - \alpha(r)^2)^3}{1 + \alpha(r)^3 + 4\alpha(r)^9}$$

(14)

maps the semi-infinite interval of $\alpha$ to the interval $[0,1]$. This form of $\alpha$ coincides with the GGA-weighting function of the MS2 functional. The physical constraints introduced for MCML are also applied to our functional, i.e., the LDA limit with $F_X = 1$ for $s = 0$ and $\alpha = 1$, the exchange gradient expansion for $s \approx 0$ at $\alpha = 1$, and the cancellation of the spurious Hartree energy in the H atom for $\alpha = 0$. The LDA limit is enforced via

$$\sum_{i=0}^{7} \sum_{k=0}^{3} (-1)^{i+k} \frac{(2k)!}{2^{2k}(k!)^2} c_{i,2k} = 1,$$

(15)

while the exchange gradient expansion is described with a curvature of $2\mu^{GE}$ for $s \approx 0$ at $\alpha = 1$

$$\sum_{i=0}^{7} \sum_{k=0}^{3} (-1)^{i+k} \frac{(2k)!}{2^{2k}(k!)^2} \frac{2i(i+1)}{\eta} c_{i,2k} = 2\mu^{GE}.$$

(16)

The spurious Hartree energy of the hydrogen atom of $\frac{\hbar}{2\Theta} E_H$ is cancelled with

$$\left(\frac{162}{\pi^2}\right)^{\frac{1}{2}} \sum_{i=0}^{7} \sum_{j=0}^{7} \int dr r^2 y^2 P_i(s^H) c_{ij} = \frac{5}{16},$$

(17)

where $y = \exp(-4r/3)$, $s^H = 2p/|\eta + p| - 1$, and $p = s^2 = (6\pi)^{-2/3}/y$ is the square of the reduced density gradient of the 1s hydrogen atom ground state.

B. Regularized optimization of $F_X$ We extend the approach introduced in Brown et al. [1] by including the vdW description via rVV10. The vdW description is optimized based on the functional form, after which our exchange functional is optimized based on a given vdW parameterization. MCML is used a starting point for the optimization. We took the product of the non-self-consistent (non-SCF) MAEs for all data sets as the cost function used for the optimization. These nonSCF predictions are explained in Brown et al. [1] and are briefly outlined in the SI, Sec. 3. The cost function

$$\theta = \prod_{i} (MAE_{i})^{-w_{i}}$$

(18)

was minimized using the Nelder-Mead simplex algorithm [26,27] raising each MAE to a weight $w_{i}$. Adjusting the weights results in different fits (see Section IV C), and enables tuning trade-offs in performance for different data sets against each other.

C. Choosing weights The weights were chosen according to Fig. 2 As

![Diagram of weight adjustment process](image)

FIG. 2. Adjustment of the weights in the functional optimization, see Eq. (15). Here, $\delta_{i}$ are thresholds for each data set, while $w_{i}$ are the corresponding weights. The evaluation was done 100 times and the best weights, i.e., the best compromise for all nonSCF MAEs, was taken for further evaluation.

A starting point, all weights were set to 1. The functional form is optimized, and the nonSCF predictions of the MAE for each data set are computed. If an MAE is beyond a predefined threshold, the weight for the data set is increased (see SI, Tab. ST1 for values). After this modification, the functional is optimized once again and the process starts anew. This outer-loop optimization was run 100 times. The best possible weights, i.e., the best compromise between all predicted MAEs, were adjusted to minimize the errors further. The final weights (see SI, Tab. ST2) were then taken to obtain the optimal $c_{ij}$ (see SI, Tab. ST3).
D. Enforce smoothness

FIG. 3. $F_X$ as well as the first and second derivative of $F_X$ with respect to the reduced density gradient $s$ at $\alpha = 0$ for VCML, which is the semilocal exchange part of VCML-rVV10. While $dF_X/ds$ shows exactly one sign change, $d^2F_X/ds^2$ shows two. As such, the regularizations work as intended, and enforce a certain smoothness of the functional.

To avoid oscillatory behavior of high-order polynomial fits, the $F_X$ is enforced to be smooth by penalizing the number of sign changes beyond given thresholds in the first and second derivatives of $F_X$ with respect to $s$ and $\alpha$. A penalty is added if there is more than one sign change in the first derivatives (which allows the exchange enhancement factor to have one extremum in $s$ for a given $\alpha$) and if there are more than two sign changes in the second derivatives (the functional should go smoothly towards and away from the extremum). Derivatives of the Legendre polynomials used to expand $F_X$ are efficiently computed via recursion, and the zeros of the resulting polynomials corresponding to the first and second derivatives are obtained as the eigenvalues of the companion matrices. This sign-change penalty technique enables us to enforce smoothness of $F_X$ in a computationally straightforward way (note that there are different mathematical forms of $F_X$ not based on polynomial expansions allowing for other techniques to enforce constraints and smoothness\cite{13}). As an example, the first and second derivative of $F_X$ with respect to $s$ at $\alpha = 0$ (single orbital limit) for VCML, the semilocal exchange part of VCML-rVV10, are shown in Fig. 3. As one can see, the proposed regularizations work as intended in making the functional smooth.

E. Summary of entire procedure to obtain VCML

Fig. 4 summarizes the fitting procedure. It starts by taking the MCML functional and determining the optimal $b$ parameter for rVV10. For this, the equilibrium structures of S66x8 (see Section V) and their resulting errors were used to optimize $b$ by scanning through a range of different $b$ values (ranging from 3

---

**FIG. 4.** Procedure to arrive at the VCML-rVV10 functional form. Starting from MCML, the optimal $b$ parameter of the rVV10 methodology is determined. The resulting MCML-rVV10 functional is used to compute all data sets self-consistently. Based on these results, the functional form was adjusted according to the minimization of Eq. 18. The adjustment of the weights is illustrated in Fig. 2. This results in an intermediate functional form, called Fit1-rVV10. For this functional, the $b$ parameter was re-optimized, and all data sets were recalculated self-consistently. Finally, the functional form was re-optimized once again, resulting in VCML-rVV10. Due to careful consideration of the errors in S66x8 as described in the SI, Sec. 3, the $b$ parameter needs no further optimization.
to 25 with a stepsize of 1). The optimal parameter, $b = 18$, defines MCML-rVV10. After calculating all data sets (see Section V) with MCML-rVV10, the functional form was re-optimized using the methodology outlined above. This led to an intermediate functional form, Fit1-rVV10.

For Fit1-rVV10, the $b$ value was re-optimized, using a smaller range ($b$ values between 13 and 21) and a smaller stepsize (0.25). From this search, an optimal $b$ value of 15.35 was interpolated. After that, all properties of all data sets were recalculated self-consistently. The resulting data is used once again to re-optimize the functional form. For this final optimization, we made sure that the non-SCF errors for the S66x8 remain small (see SI, Sec. 3 for further details), which avoids re-optimizing the $b$ parameter. Accordingly, the $b$ parameter for the final VCML-rVV10 functional is also 15.35. This functional was then used to obtain the physical properties of all data sets.

In summary, the $b$ parameter as well as the functional form were optimized twice, starting from MCML. Given an overall good performance of VCML-rVV10 in comparison to MCML-rVV10 and other functionals (see Sec. VI), we terminate the functional optimization loop here.

V. BENCHMARK DATA SETS

To obtain a multi-purpose XC functional from the proposed methodology, a variety of training data is required. Our training data consists of molecular, surface as well as bulk properties, as described below. The systems of each data set and all calculated properties are provided in the SI, Tab. ST6-26.

DBH24 The DBH24 set consists of 12 forward and 12 reverse reaction barrier heights of small molecules. Reference values are the best estimates, consisting of quantum chemical and experimental data, according to Zheng et al.[15]

Total energies were computed on the reference structures; no structural optimizations were carried out.

RE42 The RE42 set contains 42 reaction energies involving 45 molecules of the G2/97[20] test set. Experimental reference values are taken from Wellendorff et al.[21] The geometries of all molecules were fully optimized before their total energy was used to calculate the reaction energies.

S66x8 The S66x8 set has 66 molecular complexes at eight distances, the interaction of which is dominated by non-covalent bonding. Reference values are the recommended dissociation energies, calculated by MP2-F12 energies at the basis set limit combined with CCSD(T)-F12 correlation, according to Brauer et al.[12]

Total energies were computed at the reference geometries, thus no geometry optimizations were carried out.

W4-11 The W4-11 set contains 140 atomization energies of small to medium sized molecules. Reference values are taken from Karton et al.[19] which are based on the Weizmann-4 (W4) computational thermochemistry method. No structural optimizations were carried out, and total energies were computed on the reference structures.

SOL62 The SOL62 set is based on a set of 64 solids proposed by Zhang et al.[16] Of that set we removed all elements heavier than Au, as for those systems (Pb, Th) the predicted errors will typically be very large due to strong relativistic effects.[22] The reference values are taken from the supplemental information of Zhang et al.[15] where zero-point energy corrections of PBE were subtracted from the experimental values. All unit cells were fully optimized. Afterwards, the lattice constants $a_{lat}$ and bulk moduli $B$ were computed using an equation of state (EOS) fit from five energies around and at the minimum volume. Further, cohesive energies $E_{coh}$ were computed with respect to the isolated atoms in their energetically preferred magnetic ground state. This data set is split into the three subset $a_{lat}@SOL62$, $E_{coh}@SOL62$ and $B@SOL62$.

ADS41 The ADS41 set consists of 41 surface reaction energies. Experimental reference values are taken from the collection in Sharada et al.[19] The atomic positions of the isolated molecules, the isolated surfaces as well as the combined systems were optimized. For the clean surfaces and the combined systems, the cell was constrained to the bulk lattice dimensions, while introducing at least 15 Å of vacuum in the out-of-plane direction. The vacuum layer is the same for the isolated surface and the combined system, ensuring consistent results. The surfaces are constructed to have 4 layers. The lower two are fixed at the bulk lattice positions, while the top two layers (and the adsorbed molecule) are optimized. Adsorption energies are computed per adsorbate, thus the total adsorption energy is divided by the number of adsorbates in the computational cell. Because ADS41 contains Co and Ru surfaces, we additionally optimized the unit cells of either hcp solid to obtain the corresponding lattice constants. These solids are not part of the SOL62 set, and were only optimized for
The ADS41 data set is subdivided into physisorption-dominated reactions (15 reaction energies, denoted as Physi@ADS41) and chemisorption-dominated reactions (26 reaction energies, denoted as Chemi@ADS41).

VI. RESULTS AND DISCUSSION

A. Comparing $F_X$ to other functionals

The $F_X$ of MS2, SCAN, MCML as well as the new VCML are plotted in Fig. 5. In certain regions of $s$ and $\alpha$, VCML is similar to MS2, e.g., $F_X(s = 0, \alpha > 0.5)$. On the other hand, VCML is similar to SCAN for $F_X(s > 8, \alpha = 1)$. While the VCML and MCML exchange enhancement factor are similar for low reduced density gradients, the VCML exchange enhancement is markedly larger at reduced density gradients $s \gtrsim 2$. The maximum value of VCML’s $F_X$ is 1.432, which is well below the Lieb-Oxford bound of 1.804. Note that remaining below this bound was not explicitly enforced, nor was the decaying behavior with increasing $s$.

B. Performance on data sets

A summary of the MAEs for all data sets using the functionals described in the main text is shown in Fig. 6 (for values of MEs and MAEs see SI, Tab. ST4 and ST5).

Overall, our VCML-rVV10 functional shows small errors for a range of different physical properties, confirming that we have created a multi-purpose functional. It should be noted that our fitting approach favors errors of certain data sets over others. There is always a compromise between making a specific error better, while making some other error(s) worse. Accordingly, the improvements seen for VCML-rVV10 over, e.g., MCML is the best overall compromise we found. For a more detailed analysis of the resulting errors, see below.

DBH24 VCML-rVV10 performs best for DBH24, followed by MS2. Barrier heights are poorly described in DFT approximations based on semi-local exchange; all functionals produce a relatively large error for the barriers due to large self-interaction error in the regime of stretched bonds.

RE42 For the reaction energies in RE42, again VCML-rVV10 performs best, followed by r^2SCAN. Thus, the description of the reaction between molecules is described well by VCML-rVV10.

S66x8 For the S66x8 data set, SCAN-rVV10, MCML-rVV10 and VCML-rVV10 perform similarly, and clearly outperform any functional that does not include the rVV10 correction. This is a proof of concept that the rVV10 methodology works as intended. It furthermore shows that refitting the functional form from MCML to VCML did not compromise the prediction of these non-covalent interactions.

W4-11 In W4-11, we find a poor performance of VCML-rVV10. As noted in Brown et al., MCML performs worse on atomization energies than other tested functionals, which can also be seen in Fig. 6. With VCML-rVV10, we actually improve the MAE by about 20 meV.
however, the improvement of the atomization energies is limited without compromising the predictions of the other data sets too much, especially of Chemi@ADS41 and $E_{\text{coh}}@\text{SOL62}$.

Looking at $q_{\text{lat}}@\text{SOL62}$, VCML-rVV10 performs very similar to the other meta-GGAs (all performing well on lattice constants) with differences in their MAE of at most 0.005 Å. We furthermore find that VCML-rVV10 outperforms MCML as well as MCML-rVV10 for $E_{\text{coh}}@\text{SOL62}$. MCML is not an optimal functional for the description of cohesive energies; adding rVV10 on-top makes matters worse. Due to the fact that we reshaped the functional form, we arrive at an MAE which is only about 10 meV worse than SCAN-rVV10, but already 15 meV better than MCML.

For $B@\text{SOL62}$, VCML-rVV10 is the second best functional after $r^2\text{SCAN}$, clearly outperforming the other functionals that employ vdW-corrections in the form of rVV10. Overall, VCML-rVV10 performs well for solids regarding the three properties studied here; we do not diminish the performance on the solid properties and thus maintain the multi-purpose character for the application of VCML-rVV10.

Finally, for ADS41 we obtain the smallest errors in the physisorption-dominated systems using VCML-rVV10, outperforming MCML-rVV10 and SCAN-rVV10. All functionals without rVV10 have (unsurprisingly) larger errors.

For chemisorption-dominated systems, VCML-rVV10 performs significantly better than all other vdW-supplemented meta-GGAs considered here; the resulting MAE is a good as MS2. As such, VCML-rVV10 is the second best functional (together with MS2) for these systems; only MCML gives smaller errors (at the price of not explicitly accounting for dispersion forces).

For all data sets it is clear that only adding rVV10 on-top of MCML (yielding MCML-rVV10) does not provide a good vdW-meta-GGA functional. Reshaping the functional form based on a given vdW correction drastically improves the performance of the functional, making it applicable to a wide range of physical properties while also treating non-local interactions via the rVV10 methodology.

### C. Graphene on Ni

To test VCML-rVV10 outside of the training data shown in Fig. 6, we calculated the interaction energy of graphene on a Ni(111) surface. Previous theoreti-
ical investigations found that there likely are two distinct minima. These minima can be characterized as a chemisorption minimum at a smaller distance between graphene and Ni, and a physisorption minimum at a larger distance. In experiments, usually only the first minimum is found. In the literature, reference calculations have been carried out using the random phase approximation (RPA). It has been noted that the RPA is likely to underestimate the chemisorption minimum, which can be seen when comparing to experimental estimates that are shown as the grey cross in Fig. 7. The second minimum, on the other hand, is likely captured well by the RPA.

![Interaction energy of graphene on Ni(111) at several distances using different functionals. Only MCML-rVV10 and VCML-rVV10 capture the energy of the first minimum correctly, while VCML-rVV10 is also energetically very close to the RPA for the second, physisorption-dominated minimum. The shaded area indicates ±1 standard deviation calculated from a Bayesian ensemble of 5000 perturbations to the VCML exchange enhancement.](image)

In this work, a new meta-GGA van der Waals (vdW) exchange-correlation (XC) functional called VCML-rVV10 is introduced. This functional is obtained by a simultaneous optimization of both semi-local exchange via a multi-parameter model and non-local correlation of rVV10-type. VCML-rVV10 was trained on a number of data sets representing several chemical and physical properties, enabling the multi-purpose character of the functional. In addition, several constraints of the exact XC functional were enforced for physicality of the VCML-rVV10 model.

The newly introduced functional shows good performance in comparison to all other functionals tested, some of which also employing the rVV10 methodology. It also performs very well on the description of graphene on Ni(111), which was not included in the training data. This benchmark system requires a balanced, accurate description of surface properties.
physisorption as well as chemisorption.

In the future, the introduced methodology of simultaneous, regularized optimization of several parts of an XC functional could be extended to hybrid functionals, where a to-be-ﬁtted amount of screened exact exchange would be admixed to the to-be-optimized density functional.

VIII. ACKNOWLEDGEMENT

This research was supported by the U.S. Department of Energy, Ofﬁce of Science, Ofﬁce of Basic Energy Sciences, Chemical Sciences, Geosciences, and Biosciences Division, Catalysis Science Program to the SUNCAT Center for Interface Science and Catalysis. We greatly appreciate the help of James Furness for providing a patch for VASP making $r^2$SCAN available.

IX. SUPPORTING INFORMATION

- Further details for $r$VV10
- Visualization of transformation of $s$ and $\alpha$
- Details of the functional ﬁtting procedure
- Fitting weights
- Final coefﬁcients $c_{ij}$
- Tables for mean and mean absolute errors
- Tables with all calculated values
- Figures with all evaluated errors

X. DATA AVAILABILITY STATEMENT

All data, including the VASP inputs/outputs as well as all calculated values, are available at GitLab [https://gitlab.com/kaitrepte/vcml_data](https://gitlab.com/kaitrepte/vcml_data). The ADS41 adsorbate system structures can also be found on catalysis-hub, see [https://www.catalysis-hub.org/publications/KaiData-driven2022](https://www.catalysis-hub.org/publications/KaiData-driven2022).
