ABSTRACT

Ferroelectric and ferromagnetic orders rarely coexist, and magnetoelectric coupling is even more scarce. A possible avenue for combining these orders is by interface design, where orders formed at the constituent materials can overlap and interact. Using a combination of magneto-transport and scanning SQUID measurements, we explore the interactions between ferroelectricity, magnetism, and the 2D electron system (2DES) formed at the novel LaAlO$_3$/EuTiO$_3$/Sr$_{0.99}$Ca$_{0.01}$TiO$_3$ heterostructure. We find that the electrons at the interface experience magnetic scattering appearing along with a diverging Curie-Weiss-type susceptibility at low temperatures. We interpret the magneto-electric-transport properties in the framework of a 2D polar metal affected by scattering off quantum interference device (SQUID) microscopy. We find a diverging Curie-Weiss-type susceptibility at low temperatures appearing along with with a $\ln(1/T)$ term in the sheet resistance. We interpret the magneto-electric-transport properties in the framework of a 2D polar metal affected by scattering off quantum interference device (SQUID) microscopy. We find a diverging Curie-Weiss-type susceptibility at low temperatures appearing along with with a $\ln(1/T)$ term in the sheet resistance.

Results

Heterostructure design: Our goal in this work is to realize a conducting interface exhibiting both ferroelectric and magnetic properties. To design such a system we chose three components:

1. Ferroelectric CSTO, which will serve as the substrate for the heterostructure

2. A thin two-unit cell layer of magnetic ETO
3. Eight-unit cells of LAO, which induce conductivity at the interface

The resulting heterostructure can be seen in figure 1 (a), where we show Scanning-Tunneling-Electron-Microscopy (STEM) imaging along with Electron-Energy-Loss-Spectroscopy (EELS) measurements, verifying the expected structure and composition of our heterostructure (further details are shown in supplementary figure S1).

The interface is metalic at high temperatures (Figure 1 (b), bottom panel, red). Upon further cooling of the heterostructure, two distinct features can be observed - an upturn to the resistance below the ferroelectric transition, and a $\ln(1/T)$ term becoming dominant at low temperatures (highlighted in inset of bottom panel). As we elaborate below, we relate both of these terms to interactions of the 2D electron system (2DES) with the ferroelectric bulk and the magnetic ETO layer.

**Ferroelectricity:** We begin by characterizing ferroelectricity in the bulk CSTO crystal. The dielectric constant is extracted by capacitance measurements and is presented in Figure 1 (b) (top panel, blue). A ferroelectric transition is observed at $\sim 30K$, as expected for one percent Ca substitution.

The ferroelectric transition has a dramatic effect on the interface resistance. As can be seen in 1 (b) (bottom panel), the interface resistance increases as temperature is lowered into the ferroelectric phase. We have previously interpreted similar upturn in resistance as a result of the interaction between the ferroelectric bulk and the conducting polar interface. Furthermore, as temperature is lowered deeper into the ferroelectric phase, resistance versus back-gate voltage hysteresis loops are observed (Figure 2), demonstrating ferroelectric control of the 2DES. The area of these loops increases as temperature is lowered, as previously reported for 2D polar metals formed at CSTO-based interfaces.

**Magnetism:** In figure 3 (a)-(b) we present spatial susceptibility measurements of our interface at 1.8K and 5K respectively. The signal is mostly isotropic and only changes at imperfections on the interface (black regions in figure 3 (a)-(b)), where the magnetic signal, as well as the conductivity, are substantially weaker (see supplementary figure S2 for more details).

To quantify the evolution of the magnetic signal with temperature, we perform a Curie-Weiss fit to the susceptibility measurements (solid line in figure 3 (c)):

$$\frac{1}{\chi_d} = \frac{3K_n}{\mu_0(2J+1)} \frac{1}{n_s} (T - T_C)$$

Where $\chi$ is unit-less susceptibility, $d$ is the thickness of the magnetic layer, $J$ is the nuclear spin number, $n_s$ is the spin density and $T_C$ is the Curie temperature.

We can now extract the spin density $n_s$ from the fit to find the origin of the magnetic response. If we assume $J = \frac{7}{2}$ (i.e. that the magnetic signal originates from the Eu atoms) we receive a spin density of $n_s = 8.2 \cdot 10^{14} \frac{1}{cm^2}$, which is the expected order of the number of Eu atoms. However, if we assume $J = \frac{1}{2}$ (i.e. that the magnetic signal originates from the...
Figure 2. Temperature Evolution of Resistance Versus Gate Hysteresis Sheet resistance response to applied back gate voltage shows hysteretic behaviour below the ferroelectric transition. This hysteresis becomes larger as temperature is lowered deeper into the ferroelectric phase, demonstrating control of interface resistance by ferroelectric switching.

2DES), we receive a spin density of \( n_s = 1.7 \cdot 10^{16} \text{ cm}^{-2} \), which can be ruled out since it is two orders of magnitude larger than the overestimated carrier density of half an electron per unit cell \(^9\).

We note that the spin densities calculated here are lower limits as the susceptibility was measured with respect to the imperfections on the sample, which have a much weaker yet non-zero signal. By subtracting the background signal away from the sample we can set a more realistic estimation for the signal of \( 1.4 \cdot 10^{15} \text{ cm}^{-2} \) for \( J = \frac{7}{2} \). However, this estimation is hindered by noise (experimental limitations, see supplementary figure S3 for more information). We therefore conclude that for \( J = \frac{7}{2} \), the spin density is larger than \( 8.2 \cdot 10^{14} \), likely around \( 1.4 \cdot 10^{15} \text{ cm}^{-2} \). This value is in excellent agreement with the expected density of Eu atoms within two-unit cells of ETO (\( 1.3 \cdot 10^{15} \text{ cm}^{-2} \)), further confirming the magnetic signal originates from the ETO layer.

The Curie-Weiss behaviour persists down to the 1.7K (our SQUID experimental base temperature), with no clear signs of a magnetic phase transition. Interestingly, the \( \ln(\frac{1}{T}) \) term in the interface resistance is observed at the same temperature range. We interpret this behaviour as a signature of magnetic fluctuations in the ETO layer scattering conduction electrons in the 2DES. This view is consistent with the magnetoresistance (MR) measurements showed below.

In figure 4 (a), we present resistance versus magnetic field measurements with field perpendicular to the interface at different temperatures. The sign of the MR depends on both field magnitude and temperature. We interpret this behaviour as a result two competing effects: a negative spin MR, resulting from interactions with the magnetic ETO layer, and a positive, orbital quadratic term. At low temperatures, the spin component is stronger while at sufficiently high magnetic fields, the quadratic component dominates.

To quantify the spin and orbital contributions, we rotate the sample at a constant magnetic field of 14T. The resulting MR(\( \theta \)) measurements are presented in figure 4 (b), where \( \theta \) is the angle between the field and the interface. For \( 70^\circ \leq \theta \leq 110^\circ \), we assume that the magnetic anisotropy is negligible, hence we fit the data in this regime to \( \alpha + \beta \cdot \sin^2(\theta) \), where \( \alpha \) and \( \beta \) are constants representing the magnitude of the spin and orbital effects respectively. The resulting orbital component is presented in supplementary figure S8. We then subtract this positive component from the original signal to obtain the spin contribution (figure 4 (c)). We find that the spin component is negative and becomes stronger as the temperature is lowered, as expected for
magnetic fluctuations increasing at low temperatures. Furthermore, we observe an anisotropy of the spin component as $\theta$ approaches zero (in-plane magnetic field), reflecting the 2D nature of the ETO layer.

The magnitude of both spin and orbital components can be tuned by gate voltage. This is demonstrated in Figure 4 (d) where we performed field rotation measurements at 2K at various gate voltages. Using similar analysis as in Figure 4 (b)-(c), we find that the spin component increases in magnitude as electrons are depleted (negative gate voltage) from the 2DES (Figure 4 (e)). As we elaborate in the discussion section, we relate this result to a change in position of the 2DES relative to the interface as function of carrier concentration.

While the results presented above point to magnetic fluctuations in the ETO layer scattering electrons in the 2DES, we find no evidence of the 2DES altering magnetism in the ETO layer, as one would expect from an RKKY-type magnetism. This can be seen in supplementary Figure S7, where susceptibility maps are measured at different back-gate voltages. We find that the susceptibility is independent on carrier density within resolution.

To further examine the effect of conduction electrons on magnetism, we performed similar scanning SQUID measurements for non-ferroelectric LAO/ETO/STO heterostructures. Two samples were studied - a conducting sample with a two-unit-cell thick layer of ETO at the interface and another sample with five-unit cells of ETO, which results in an insulating interface. Susceptibility versus back-gate voltage measurement were performed for the conducting sample, showing no effect of carrier modulation on the magnetic response (supplementary Figure S7). We note that our transport study reproduce previous results on the LAO/ETO/STO interface \(^{18}\) (supplementary Figure S5). The insulating sample studied here shows qualitatively similar results to the conducting samples (supplementary figure S6 (b)). These results further imply that the 2DES formed at these interfaces does not play a role in inducing magnetism in the thin ETO layer.

We now move to the question of the magnetic ground state of the thin ETO layer. For either a ferromagnetic or antiferromagnetic phase transition, one would expect a saturation of the magnetic susceptibility below the transition temperature. However, no such saturation is observed, suggesting that the ETO does not undergo magnetic ordering down to 1.7K. This observation is further supported by the zero-field spatial magnetic imaging produced at 1.7K, which shows no evidence of ferromagnetic domains (supplementary figure S2 (a)). An in-plane aligned magnetization is also ruled out, since fringing field lines from such domains would have been picked up at the presumed domain boundaries. These observations also hold for the non-ferroelectric LAO/ETO/STO interfaces studied here (see supplementary figures S2 (b) and S6 (a)).

No clear indication of a magnetic phase transition is vis-

---

**Figure 4. Low Temperature Magnetoresistance (MR) Measurements** (a) Symmetrized resistance versus out-of-plane magnetic field for different temperatures. (b) MR magnitude at 14T for different temperatures and angles between the interface and the field ($\theta$). (c) MR magnitude after subtraction of extrapolated orbital effect. This remaining effect illustrates the MR spin component. (d) MR magnitude at 2K for different back-gate voltages and angles $\theta$. (e) Gate-dependant spin contribution achieved similarly to (c). This term becomes more dominant at negative gates (electron depletion).
ible in transport. This can be seen by the $\ln(\frac{1}{T})$ upturn to the interface resistance, showing no saturation down $\sim$20mK. Typically, magnetic ordering is accompanied by a saturation of such a resistance upturn, as can be observed for example in systems such as doped ETO$^{11-14}$ and manganites$^{22,23}$. Furthermore, no magnetic hysteresis is visible at 0.5K (supplementary figure S4), as opposed to, for example, the case of Sm doped ETO, which shows a strong hysteresis below the Curie temperature$^{14}$.

**Discussion**

In figure 1 (c) we sketch our understanding of how ferroelectricity and magnetism interact with the 2DES in the LAO/ETO/CSTO heterostructure. The conduction electrons reside at the edge of the ferroelectric CSTO and are adjacent to the magnetic ETO layer. Ferroelectricity in the CSTO bulk can be switched by using the gate voltage to control the 2DES properties (Figure 2). As the temperature is lowered, magnetic fluctuations in the ETO layer increase and scatter the conduction electrons in the 2D polar metal. This scattering results in a strong negative spin-MR signal (Figure 4) and a Kondo-type temperature dependence of the resistivity (Figure 1 (b), bottom panel) appearing together with a diverging Curie-Weiss behaviour of the ETO susceptibility (Figure 3 (c)). We note that similar Kondo-type temperature dependence of the resistance and negative MR were previously observed in doped ETO$^{11-14}$ in manganites$^{22,23}$ and in electron-doped cuprates$^{24}$.

Furthermore, we show the spin MR term can be tuned by applying back-gate voltages, becoming stronger at negative gates (electron depletion, Figure 4 (e)). We explain this enhancement by the 2DES becoming spatially closer to the ETO layer, making the 2DES more susceptible to magnetic scatterings. This picture of the electrons becoming more confined to the interface at the depleted regime is in line with the calculation of Delugas et al.$^{25}$.

While the 2DES experiences magnetic scattering off magnetic fluctuations originating in the ETO layer, our observations show that the magnetism in the ETO layer is unaffected by the presence of the 2DES. This conclusion is supported by: (1) The magnetic susceptibility is independent of gate voltage (supplementary figure S7). (2) Non-conducting ETO based heterostructures show qualitatively similar magnetic measurements to the conducting samples (supplementary figures S2 and S6). (3) All ETO-based samples studied here exhibit no ferromagnetism (supplementary figure S2 (a)-(c)).

Recently, LAO/STO interfaces were fabricated with GdTiO$_3$ interlayers instead of EuTiO$_3$.$^{26}$ These interfaces present similar, gate-tunable non-linear Hall signatures to those observed in the LAO/ETO/STO interface. However, no ferromagnetic domains were found in scanning SQUID measurements.

**Summary**

In this work, we explored magnetism, ferroelectricity and their interactions with the 2D electron system formed at the LaAlO$_3$/EuTiO$_3$/Sr$_{0.99}$Ca$_{0.01}$TiO$_3$ interface. The conducting electrons in the 2DES experience magnetic scattering originating from the EuTiO$_3$ layer. This is evident from a diverging $\ln(\frac{1}{T})$ term in the interface resistance appearing at low temperatures along with a Curie-Weiss-type behaviour of the ETO susceptibility. By analysing magnetoresistance measurements, we were able to separate out the contribution of the spin scattering to the magnetoresistance. This scattering channel becomes dominant as temperature is lowered and is tunable by gate biasing, becoming stronger when electrons are depleted from the 2DES. Ferroelectricity also interacts with the 2DES as demonstrated by the hysteresis observed in sheet resistance when switching ferroelectric polarization in the bulk.

While the 2DES interacts with both ferroelectricity and magnetism, we find that the presence of conduction electrons has no effect on the magnetic susceptibility of the EuTiO$_3$ layer. Furthermore, no signs of ferromagnetism is observed in any of our EuTiO$_3$-based samples with or without ferroelectricity. Control of magnetism by electron density modulation is desired in order to realize a new type of multiferroic 2DES where ferroelectricity and magnetism can interact via an intimidating conducting layer. By selecting other magnetic materials it should be possible to achieve this desired functionality.

**Methods**

**Sample Preparation and Transport Measurements**

Two-unit cells of EuTiO$_3$ followed by eight-unit cells of LaAlO$_3$ were deposited by pulsed laser deposition on atomically flat TiO$_2$ terminated Sr$_{0.99}$Ca$_{0.01}$TiO$_3$ substrates. Both ETO and LAO were deposited in situ at a rate of 1 Hz, oxygen partial pressure of $10^{-6}$ torr, temperature of 680°C and energy density of 1.15 $\text{J} \cdot \text{cm}^{-2}$. After deposition, samples were cooled to room temperature at a rate of $\frac{3}{min}$ at the deposition environment. The same growth procedure was followed for non-ferroelectric LAO/ETO/STO interfaces studied here, varying only the thickness of the ETO layer. Back-gate electrodes were attached to the bottom of the CSTO with Ag paint. When gate voltage was applied, the leakage current was immeasurably small (<1 pA). The gate voltage is defined as positive when electrons accumulate at the interface. Measurements were performed in a PPMS system with a base temperature of 2K and magnetic fields up to 14T. Measurements below 2K were conducted in a Triton dilution refrigerator with a base temperature of 20 mK.

**Scanning SQUID Measurements**

We use a scanning SQUID microscope with a micron size sensitive area (the pick-up loop). The pick-up loop is rastered above the surface of the sample, recording the $Z$ component
of the magnetic field as a function of position\textsuperscript{27–30}, in units of flux (Φ₀). Local magnetometry, susceptometry, and current response measurements were performed simultaneously. Magnetometry mode maps the static magnetic landscape, captured by the SQUID’s pick-up loop. Susceptometry measurements are performed by applying local magnetic field with a field coil loop that surrounds the pick-up loop. In the data shown here a.c. current (0.1-3 mA RMS, 1-3 kHz) was applied to the field coil generates a local magnetic field of 0.1-3 G RMS. The pick-up loop detects magnetic signals generated by the applied field. This signal is separated from d.c. data by using a lockin. To compensate for background magnetic fields an identical pick-up loop, surrounded by an identical field coil, is located 1.2 mm away and wired in a gradiometric design. For mapping electric current flow, we capture the magnetic fields generated by the current by the pick-up loop. These signals are separated from others by using a lockin. A thread of current flow appears in a SQUID image as a negative magnetic signal next to a positive signal. We perform all scans at a fixed sensor-sample distance of ~1 μm.

Appendix

Converting SQUID measured magnetic flux by the pick-up loop (Φ_{PL}) to unitless susceptibility (χ)\(^1\):

\[ B = \mu_0 \chi d \frac{dH}{dz} = \frac{\Phi_{PL}}{\pi R_{PL}^2} \]

Where \( R_{PL} \) is the radius of the pick-up loop, and H is the magnetic field applied by the filed coil loop:

\[ H = \frac{\mu_0 R_{PL}^2}{2(z^2 + R_{FC}^2)^2} I_{FC} \]

\[ \frac{dH}{dz} = \frac{3\mu_0 R_{FC}^2}{2(z^2 + R_{FC}^2)^2} I_{FC} \]

\( I_{FC} \) is the current applied in the field coil loop, \( R_{FC} \) is the radius of the field coil loop, and \( z \) is the height of the SQUID pick-up loop above the sample.

From these we can extract \( C_g \) – the geometric constant for the conversion:

\[ \chi d = \frac{2(z^2 + R_{FC}^2)^2}{3\pi \mu_0 R_{FC}^2 R_{PL}^2} \frac{\Phi_{PL}}{I_{FC}} = \frac{\Phi_{PL}}{I_{FC}/A} \]

For \( z = 1[\mu m] \); \( R_{FC} = 6.3[\mu m] \); \( R_{PL} = 1.25[\mu m] \):

\[ C_g = 6 \times 10^{-8}[m] \]

\( R_{PL} \) and \( R_{FC} \) are the effective radius calculated from the inner and outer radiuses of the coils.
