Spin pumping converting sub-terahertz electromagnetic waves to DC spin currents has recently been demonstrated in antiferromagnets (AFMs) with easy-axis magnetic anisotropy. However, easy-plane AFMs such as NiO, which are easier to prepare experimentally, are considered to be bad candidates for spin pumping because the Néel vector oscillation is linearly polarized, placing a major restriction on the material choice for practical applications. Through a case study of NiO, we show that an applied magnetic field below the spin-flop transition can substantially modify the polarization of the resonance eigenmodes, which enables coherent sub-terahertz spin pumping as strong as that in easy-axis AFMs. In addition, we find that an applied magnetic field can significantly reduce the threshold of Néel vector auto-oscillation triggered by spin-transfer torques. These prominent field-assisted effects can greatly facilitate spintronic device engineering in the sub-terahertz frequency regime.

As an emerging frontier in physics and electrical engineering, antiferromagnetic (AFM) spintronics initiated a revived search for electronic devices operating in the terahertz (THz) frequency range, thanks to their unique physical characteristics such as ultrafast dynamics and vanishing stray fields. Recently, sub-THz spin pumping has been confirmed experimentally in easy-axis AFMs MnF$_2$ and Cr$_2$O$_3$. However, easy-plane AFM materials such as NiO and MnO, which are more abundant in nature and easier to prepare experimentally, are considered to be bad candidates for realizing spin pumping. This is because the dynamics of the Néel vector is linearly polarized, blamed on the broken rotational symmetry due to the easy-plane anisotropy. Recently, it has been demonstrated that in light of the Dzyaloshinskii–Moriya interaction, spin pumping can be achieved in easy-plane AFM α-Fe$_2$O$_3$. However, what pumps the DC spin current in α-Fe$_2$O$_3$ is the weak magnetic moment rather than the Néel vector, so the system effectively functions as a ferromagnet with an operating frequency limited to tens of gigahertz. It is still an open question as to how easy-plane AFM materials can be exploited as a general platform to realize spin pumping in the sub-THz regime, especially at room temperature. Furthermore, as a reciprocal effect of spin pumping, current-induced auto-oscillation in easy-plane AFM materials requires an impractically high current threshold because the current-induced torques cannot exhibit any damping effect before they fully counteract the impact of easy-plane anisotropy. Therefore, within our current understanding, simple room-temperature AFM materials such as NiO can hardly be practical choices for ultrafast device applications.

One way out of this dilemma, basing on pure symmetry considerations, is to compensate the broken rotational symmetry caused by the easy-plane anisotropy. Applying a magnetic field along the in-plane easy axis can achieve this goal because the Zeeman interaction bears rotational symmetry around the magnetic field. To confirm whether an applied magnetic field will enable spin pumping in easy-plane AFM materials, it is essential to figure out how the applied field can affect the polarization of the resonance modes [for field strengths below the spin-flop (SF) threshold]. However, this piece of information remains elusive even theoretically, although the dependence of resonance frequencies on an applied field has been well established.

In this Letter, we conduct a case study of NiO—a prototype of easy-plane AFM systems, to demonstrate that a bias magnetic field applied along the in-plane easy axis direction (without inducing the SF transition) can: 1) enable detectable sub-THz spin pumping by substantially modifying the polarization of sublattice spin dynamics; 2) significantly reduce the current threshold triggering auto-oscillation of the Néel vector by counteracting the influence of easy-plane anisotropy. Our findings pave the way to utilize simple room-temperature AFM materials to perform ultrafast functionalities.

Let us first consider a two-sublattice macrospin model where the two antiferromagnetically coupled magnetic moments are described by $M_1$ and $M_2$. We choose the coordinate system such that the easy-axis is along $\hat{z}$ and the hard-axis is along $\hat{x}$ (so the $x$–$y$ plane is the easy plane). In NiO, $\hat{z}$ is the (111) direction and $\hat{x}$ is the (11$\bar{2}$) direction. In terms of the unit vectors $m_1 = M_1/M_s$ and $m_2 = M_2/M_s$ with $M_s$ the saturation magnetization, the free energy density of NiO in the low temperature regime can be written as

$$\delta = Jm_1 \cdot m_2 - \frac{A}{2} [(m_1 \cdot \hat{x})^2 + (m_2 \cdot \hat{x})^2]$$

$$+ \frac{K}{2} [ (m_1 \cdot \hat{z})^2 + (m_2 \cdot \hat{z})^2 ] - M_i H \cdot (m_1 + m_2),$$

(1)

where $H$ is the applied magnetic field; $J$, $A$ and $K$ are the exchange coupling, the easy-axis and the hard-axis anisotropy, respectively, all being positive in our convention. Without otherwise stated, thermal fluctuations will be ignored throughout this Letter. The coherent dynamics of $m_1$ and $m_2$ is described by the Landau-Lifshitz-Gilbert (LLG) equations

$$\dot{m}_1 = \omega_J m_1 \times m_2 - \omega_H m_1 \times (m_1 \cdot \hat{x}) \hat{x}$$

$$+ \omega_K m_1 \times (m_1 \cdot \hat{z}) \hat{z} - \omega_H m_1 \times \hat{H} + \alpha m_1 \times \dot{m}_1, \quad (2a)$$

$$\dot{m}_2 = \omega_J m_2 \times m_1 - \omega_H m_2 \times (m_2 \cdot \hat{x}) \hat{x}$$

$$+ \omega_K m_2 \times (m_2 \cdot \hat{z}) \hat{z} - \omega_H m_2 \times \hat{H} + \alpha m_2 \times \dot{m}_2, \quad (2b)$$
where $\hat{H}$ is the unit vector of $H$, $\alpha$ is the Gilbert damping constant, $\omega_1 = J/\hbar$, $\omega_2 = A/\hbar$, $\omega_3 = K/\hbar$ and $\omega_4 = HM_s/\hbar$ are the angular frequencies corresponding to each magnetic interaction appearing in Eq. (1).

For $H$ applied to the $\hat{x}$ direction (parallel to $m_1$), we linearize the LLG equations around the equilibrium configuration, $m_{1,2} = \pm \hat{x}$, and solve the eigenfrequencies adopting material parameters of NiO. Figure 1(a) shows the eigenfrequencies of NiO, where the gap at zero field is attributed to the hard-axis anisotropy $\omega_K$. The two eigenfrequencies, dubbed acoustic and optical modes, vary non-linearly but continuously with an increasing field until the SF transition marked by the dashed green line around 7.8T. In Fig. 1(b), we plot the polarization of each eigenvector in terms of the logarithm to the base 10 of the ratio of principal axes of the elliptical trajectories for $m_1$ (red lines) and $m_2$ (blue lines), where we observe an unexpected divergence at around 0.4T—far below the SF threshold. Specifically, in the acoustic (optical) mode with relatively low (high) frequency, it is $m_1$ ($m_2$) that experiences a diverging ratio $\varepsilon_y/\varepsilon_x$ at this critical point while the polarization of $m_2$ ($m_1$) changes smoothly.

As a comparison, we also show the eigenfrequencies and the polarization of the eigenmodes in uniaxial AFM MnF$_2$. In Fig. 1(c) and (d). On the one hand, the two eigenfrequencies are degenerate at zero field and splits linearly with an increasing field until the acoustic branch almost touches zero. On the other hand, both modes are circularly polarized below the SF transition as $\log(\varepsilon_y/\varepsilon_x) = \log(10)$. To uncover the physical picture behind the unexpected divergence appearing in Fig. 1(b), we zoom in around the critical point and schematically illustrate the evolution of the precession trajectories of the two anti-parallel magnetic moments in Fig. 1(e). For the acoustic branch, $m_1$ and $m_2$ both rotate elliptically as seen against the $x$ axis, where the major (minor) axis is along $\hat{y}$ ($\hat{z}$). As the field goes across the critical point at which $\varepsilon_x/\varepsilon_y \rightarrow \infty$, the trajectory of $m_1$ shrinks and reopens with an opposite chirality whereas $m_2$ does not change its chirality. The optical branch follows a somewhat similar pattern but the polarization changes in the opposite way. Basing on Fig. 1(e), we identify a wide window of field strength (between the critical point and the SF threshold) within which the two magnetic moments precess with the same chirality—a crucial behavior for nonzero DC spin pumping. Specifically, if the two magnetic moments precess with opposite chirality, they will destructively contribute to the DC spin pumping as $m_1 \times m_1$ and $m_2 \times m_2$ are opposite in direction. The two sublattice moments become competitive in generating spin current only when they rotate in the same manner. Therefore, the occurrence of chirality flip below the SF transition could enable the realization of DC spin pumping in NiO, hence in similar easy-plane AFM materials even within the collinear phase. Moreover, we find that the critical field $H_c$ for chirality flip increases linearly with the hard-axis anisotropy $\omega_K$ as shown in the inset of Fig. 1(e).

To demonstrate the field-assisted spin pumping more pictorially, we now investigate the dynamics of the acoustic mode of NiO in Fig. 2. In Fig. 2(a), when there is no magnetic field, $m_1$ (red) and $m_2$ (blue) precess elliptically with opposite chirality, resulting in a linearly polarized Néel vector $n = (m_1 - m_2)/2$ (the trajectories have been exaggerated for visual clarity). Correspondingly, the resonance of $n$ only give rise to an AC spin pumping while the DC component vanishes identically, which is a universal problem rooted in the broken rotational symmetry of bi-axial AFM materials. In addition, the total magnetic moment $m = (m_1 + m_2)/2$ oscillates linearly in the $z$ direction, so a driving microwave field $h_{rf}$ polarized along $y$ cannot even drive the acoustic mode. However, assisted by a Zeeman field, the trajectory of $m_1$ flips its chirality across the aforementioned critical point, thereby leading to an elliptical precession of $n$ as illustrated in Fig. 2(b). Moreover, once $n$ opens up an elliptical trajectory, the total moment $m$ will also rotate elliptically with a finite projection on the $y$ direction, which can couple to and be driven by the $rf$ field. In such manner, a finite DC spin pumping is enabled, which can be detected straightforwardly by the inverse spin Hall effect (ISHE) in an adjacent heavy metal.

To quantitify the physical picture described above, we now consider a Pt/NiO bilayer heterostructure and calculate the ISHE voltage arising from coherent DC spin pumping under a fixed driving frequency $\omega$ and a sweeping magnetic field $H$. FIG. 1. (a) eigenfrequencies and (b) polarization of the eigenmodes for NiO, compared with (c) and (d)—their counterparts in MnF$_2$. (e) Zoom-in plot of (b) in the vicinity of the critical point with illustrations of precession trajectories. Inset: dependence of the critical field on the hard-axis anisotropy. Parameters: for NiO, $\omega_1 = 1.7 \times 10^{13}$, $\omega_K = 1.4 \times 10^{10}$, $\omega_A = 5.2 \times 10^8$ (rad/s), and $\alpha = 5 \times 10^{-4}$ for MnF$_2$, $\omega_K = 0$ and other parameters taken from Ref. 13.

along $\hat{x}$. For $\omega$ lying in the frequency range of the acoustic branch, the resonance field is approximately

$$\hat{H}_{\text{res}} \approx \frac{\hbar}{M_x} \sqrt{2\omega_x \omega_h - \omega^2}, \quad (3)$$

which is true in the exchange limit that $\omega_h \ll \omega_K \ll \omega_f$. By taking into account the spin diffusion and spin backflow effects and ignoring thermal excitations (e.g., spin Seebeck effect), the ISHE voltage (in the y direction) becomes

$$V_{\text{op}} = \omega \text{Im} \left[ \chi_{yy} \chi_{yz} \right] \hat{g}_r \frac{eL_D \rho_{\text{SH}}}{2\pi} \frac{\lambda}{\tan \left( \frac{d_N}{2\lambda} \right)} \left| h_{zt} \right|^2, \quad (4)$$

where $\chi_{ij} = \chi_{ij}(\omega, \hat{H}_{\text{res}})$ ($i, j$ running over $y$ and $z$) is the dynamical susceptibility tensor defined as $n_i = \chi_{ij}(\omega, \hat{H}_{\text{res}}) h_{zt}$. In Eq. (4), $\hat{g}_r$ is the real part of the spin-mixing conductance renormalized by the spin backflow effect, $e$ is the electron charge, $L$, $\rho$, $\rho_{\text{SH}}$, $\lambda$, and $d_N$ are the length, resistivity, the spin Hall angle, spin diffusion length, and thickness of the Pt layer, respectively.

Figure 2(c) plots the numerical results based on Eq. (4) for four different driving frequencies in the acoustic branch, where a lower driving frequency results in a higher spin pumping signal taking place at a higher resonance field, consistent with Eq. (3). As $H_{\text{res}}$ approaches the SF threshold, the polarization of sublattice magnetic moments, hence that of $n$, becomes increasingly circular, greatly enhancing the strength of DC spin pumping. At about 100 GHz, the amplitude of spin pumping is as large as that in a uniaxial AFM material. In the inset, we show the dependence of the ISHE voltage on the driving frequency ranging from 90 GHz to 180 GHz, which is an accessible range for microwave drive.

Given that a magnetic field can substantially compensate the broken symmetry ascribing to the bi-axial anisotropy to enable an appreciable DC spin pumping even in the collinear phase, it is natural to expect a similar remarkable field-assisted effect in the reciprocal phenomenon, namely the reduction of the current threshold triggering auto-oscillation of the Néel vector. To this end, we add the spin-transfer torque (STT) \[ \tau_i = m_i \times (\omega_x \times m_i) \] to Eq. (2) where $\omega_x = \omega_x \hat{x}$ represents the spin accumulation generated by an applied current in the y direction. Here, the STT strength, proportional to the current density, is scaled into the frequency dimension. For $\mathbf{n} = \hat{x} + (n_y \hat{y} + n_z \hat{z}) e^{i\omega t}$ and $\mathbf{m} = (m_y \hat{y} + m_z \hat{z}) e^{i\omega t}$, where $n_{yz} < 1$ and $m_{yz} \ll 1$, linearizing the LLG equations with respect to the basis $\{n_x, n_z, n_y, n_z \}$ results in an eigenvalue problem. The eigenfrequencies $\omega$ are determined by

$$\begin{bmatrix}
-i\omega & \omega_H & \omega_s & \omega_s + i\alpha \omega \\
-\omega_H & i\omega & \omega_s & 0 \\
0 & 2\omega_f + \omega_K & \omega_H & i\omega \\
-2\omega_f - \omega_H & 0 & -\omega_H & i\omega
\end{bmatrix} = 0, \quad (5)
$$

where only two of the four solutions are physically distinct while the other two are redundant. We label the two physical solutions as the acoustic mode $\omega_{ac}$ and the optical mode $\omega_{op}$. In the presence of the STT competing with the Gilbert damping, both $\omega_{ac}$ and $\omega_{op}$ are complex valued, where the real parts determine the precessional frequency and the imaginary parts determine the stability of the eigenmodes. If the imaginary part $\text{Im}[\omega]$ turns zero, the corresponding eigenmode becomes unstable, marking the onset of auto-oscillation. Figure 3(a) and (b) plot the real and imaginary parts for both modes as functions of the STT strength $\omega_s$ for $\mu_0 H = 0$ T (black curves) and $\mu_0 H = 2$ T (red curves) applied in the same direction as $\omega_s$. Note that a 2T magnetic field already surpasses the critical field so that the Néel vector acquires the left-handed chirality in $\omega_{ac}$.

For $\mu_0 H = 0$ T, $\text{Re}[\omega_{ac}]$ and $\text{Re}[\omega_{op}]$ approach each other as the STT increases until they merge at a bifurcation point, while $\text{Im}[\omega_{ac}]$ and $\text{Im}[\omega_{op}]$ are degenerate and kept constant. Beyond the bifurcation point, $\text{Im}[\omega_{ac}]$ rapidly decreases and touches zero at $\mathcal{O}$, which is only slightly above the bifurcation point. According to Ref. [21], the anti-damping effect of STT only takes place within the narrow window bounded by the bifurcation point and $\mathcal{O}$, while the vast majority of the STT counteracts the impact of the hard-axis anisotropy rather than competes directly with the Gilbert damping.

For $\mu_0 H = 2$ T, the situation changes dramatically. The bifurcation point of the imaginary parts is moved to zero, so applying an STT immediately exerts an anti-damping effect on the Néel vector, and the auto-oscillation of the acoustic mode is triggered at a much lower threshold marked as $\mathcal{O}$. 

![Figure 2](image-url)
For the real parts, the bifurcation point is also removed (in fact, be moved to infinity) by the Zeeman field such that the two modes never merge. Therefore, the field-assisted effect manifests as the elimination of the bifurcation point, hence a significant reduction of the auto-oscillation threshold where $\text{Im}[\omega_{ac}] = 0$.

Having obtained the influence of Zeeman field on the eigenfrequencies, it is natural to check the eigenvectors from which we can draw a more intuitive picture of the auto-oscillation. What is relevant to our discussion is the way magnetic moments precess around their equilibrium directions right at the auto-oscillation threshold (i.e., $\text{Im}[\omega_{ac}] = 0$). To this end, we numerically simulate the eigenvectors at $\text{threshold for } \mu_0H = 2T$ and $\text{threshold for zero field}$. Figure 3(c) and (d) show their snapshots with amplitude exaggerated for visual clarity. While they both exhibit the same chirality (left-handed) for both sublattice magnetic moments, the polarization plane enclosing the major axis of elliptical trajectories (highlighted in green) is different. The tilting angle of the polarization plane with respect to the easy plane of NiO is negligibly small for $\text{threshold for } \mu_0H = 2T$ and $\text{threshold for zero field}$. Figure 3(c) and (d) show their snapshots with amplitude exaggerated for visual clarity.

We emphasize that the Zeeman field does not directly lead to instability. It is the anti-damping effect of the STT that triggers the auto-oscillation. However, the anti-damping effect is inhibited remarkably by the hard-axis anisotropy of NiO in the absence of magnetic fields. What a Zeeman field can do is to restore the broken rotational symmetry by suppressing the hard-axis anisotropy $\omega_K$, thereby assisting the STT to overcome the Gilbert damping (i.e., anti-damping effect).

Finally, we quantify the field-assisted auto-oscillation by calculating the threshold STT $\omega_{th}^s$ as a function of the applied magnetic field for different Gilbert damping constants. As shown in Fig. 3(e), the threshold STT $\omega_{th}^s$ decreases monotonically with an increasing magnetic field; this field-assisted reduction is more compelling for smaller Gilbert damping. For example, using the experimental value $\alpha = 5 \times 10^{-4}$, we estimate that a magnetic field of 6T can reduce $\omega_{th}^s$ by more than one order of magnitude (red curve). For even smaller damping, e.g., $\alpha = 1 \times 10^{-4}$, $\omega_{th}^s$ is reduced by almost two orders of magnitude at 6T. Moreover, $\omega_{th}^s$ is an asymmetric function of $H$: the reduction is more prominent for positive $H$ (when Zeeman field is parallel to the current-induced spin accumulation $\omega_s$). This asymmetry is reflected more clearly in the output auto-oscillation frequency as plotted in Fig. 3(f). Specifically, the in-plane mode will be excited by the STT when the magnetic field is parallel (antiparallel) to the spin accumulation $\omega_s$. The output frequency as a function of $H$ is almost independent of $\alpha$ above 2T (1T) for positive (negative) magnetic field, as shown Fig. 3(f). This is because once an auto-oscillation is triggered, its output frequency is determined by the real part of the eigenfrequency that is insensitive to the Gilbert damping.

26Note that in Ref. we overestimated so that the auto-oscillation threshold and the bifurcation point are not too close to each other. However, a more recent experiment shows that is only about 5 × 10⁻⁴, which we adopted in this Letter, thus is only slightly above the bifurcation point.
