Abstract

We consider the problem of sequential sparse subset selections in an online learning setup. Assume that the set $[N]$ consists of $N$ distinct elements. On the $t$th round, a monotone reward function $f_t : 2^{[N]} \rightarrow \mathbb{R}_+$, which assigns a non-negative reward to each subset of $[N]$, is revealed to a learner. The learner selects (perhaps randomly) a subset $S_t \subseteq [N]$ of $k$ elements before the reward function $f_t$ for that round is revealed ($k \leq N$). As a consequence of its choice, the learner receives a reward of $f_t(S_t)$ on the $t$th round. The learner’s goal is to design an online subset selection policy to maximize its expected cumulative reward accrued over a given time horizon. In this connection, we propose an online learning policy called SCORE (Subset Selection with Core) that solves the problem for a large class of reward functions. The proposed SCORE policy is based on a new concept of $\alpha$-CORE, which is a generalization of the notion of Core from the cooperative game theory literature. We establish a learning guarantee for the SCORE policy in terms of a new performance metric called $\alpha$-augmented regret. In this new metric, the power of the offline benchmark is suitably augmented compared to the online policy. We give several illustrative examples to show that a broad class of reward functions, including submodular, can be efficiently learned with the SCORE policy. We also outline how the SCORE policy can be used under a semi-bandit feedback model and conclude the paper with a number of open problems.

Keywords: Online algorithms, Core of a game, Subset selection

1. Introduction

The term Subset Selection refers to a broad family of computational problems where the overall goal is to efficiently select a small number of elements from a larger set to approximately maximize a monotone set function. Optimal subset selection is fundamental to many tasks in AI and ML, including feature selection (Khanna et al., 2017), coreset selection (Borsos et al., 2020), sparse regression (Kale et al., 2017), and viral marketing in social networks (Kempe et al., 2003). Because of its practical importance and theoretical elegance, both the offline and online variants of the subset selection problem have been extensively investigated in the literature in various settings. We refer the readers to Section 7 for a brief survey of the related works. In the online setting, a particular case of the problem is the classic Prediction with Expert advice, where the learner randomly selects only one expert from the set of $N$ experts at each round to optimize a linear reward function (Cesa-Bianchi and Lugosi, 2006). In this paper, we consider the general problem of sequentially selecting a subset of $k$ elements from a universe of $N$ elements at each round to maximize the sum

*In the above table $\epsilon$ denotes the accuracy parameter, SFM denotes the time complexity for minimizing a submodular function (Harvey et al., 2020), and CFS($\alpha$) represents the time complexity for finding an $\alpha$-admissible vector for a reward function. The approximation ratio $\gamma$ is stated with reference to the corresponding minimax regret lower bound.

** Augmented regret bound. See Eqn. (8) for the definition.

of a sequence of non-negative monotone reward functions by minimizing a new performance metric called $\alpha$-augmented regret. The reward functions, which could be adversarially chosen, are revealed to the learner at the end of each round in an online fashion.

In the particular case when the reward functions are submodular, Streeter and Golovin (2008) designed the first online policy with a sublinear regret for the subset selection problem. Their proposed policy greedily runs $k$ instances of the expert algorithm at each round. Several follow-up works have extended the scope and improved the complexity of their original policy. See Table 1 for a comparison of our proposed SCORE policy with other existing solutions.

Our Contributions

In this paper, we make the following contributions:

1. In Section 3, we introduce the concept of $\alpha$-CORE - a generalization of CORE from cooperative game theory. We present a dual characterization of $\alpha$-CORE in Theorem 3, which is used to derive sufficient conditions for the existence of a non-empty $\alpha$-CORE in Proposition 12.

2. In Section 4, we propose a new online subset selection policy called SCORE. Theorem 5 gives a dimension-free learning guarantee for SCORE in terms of the common $\alpha$-CORE of the reward function sequence. The flexibility of our framework allows us to utilize results from the game theory literature in the online learning setup. Section 5 gives several examples to show that SCORE can efficiently learn a broad class of reward functions of significant practical importance.

3. We study a new regret metric, called augmented regret, where the benchmark is taken to be a fraction of the maximum cumulative reward that could possibly be obtained by selecting all elements at each round. Unlike the static or dynamic regret, the augmented regret metric does not depend on any specific ad hoc choice of the offline benchmark and might be of independent interest. A similar measure, named resource augmentation, has previously been used in the competitive analysis of online algorithms (Sleator and Tarjan, 1985).

2
2. Preliminaries

We begin with the simpler linear-reward version of the subset selection problem considered earlier by Mukhopadhyay et al. (2022). In this problem, the adversary chooses a linear (i.e., modular) function \( f_t(S) := \sum_{i \in S} g_{t,i} \), \( \forall S \subseteq [N] \) at every round \( t \). The learner randomly selects a subset \( S \) containing \( k \) elements with probability \( p_t(S) \), \( S \subseteq [N] \), and receives an expected reward of \( \sum_S p_t(S) f_t(S) \) on the \( t^{th} \) round. The reward function \( f_t \) (equivalently, the coefficient vector \( g_t \)) is revealed to the learner at the end of round \( t \), \( \forall t \geq 1 \). The learner’s objective is to maximize its cumulative reward accrued over a horizon of length \( T \). In their paper, Mukhopadhyay et al. (2022) made two key observations about this problem:

1. Because of the linearity of the reward function \( f_t \), the expected reward at any round depends only on the marginal inclusion probabilities of the elements, i.e.,
   \[
   \mathbb{E}[f_t(S)] = \sum_{i=1}^{N} p_t(i) g_{t,i},
   \]
   where \( p_t(i) \) is the marginal inclusion probability of the \( i^{th} \) element in the sampled subset \( S_t \).

2. The following two conditions (2) and (3) are necessary and sufficient for a vector \( q \) to correspond to the marginal inclusion probabilities induced by some sampling scheme that samples \( k \) elements from \( N \) elements without replacement:
   \[
   \sum_{i=1}^{N} q_i = k, \quad 0 \leq q_i \leq 1, \quad \forall i \in [N].
   \]

In other words, conditions (2) and (3) are equivalent to the existence of a sampling distribution \( \{p(S), S \subseteq [N]\} \), such that
   \[
   \sum_{S \mid |S| = k} p(S) = 1 \quad \text{and} \quad q_i = \sum_{S \ni i} p(S), \quad \forall i \in [N].
   \]

The necessity of condition 3 is obvious. Furthermore, since the online policy samples exactly \( k \) elements without replacement, condition 2 follows by enforcing this condition in expectation. Let \( \Delta_k^N \) denote the set of all vectors satisfying requirements (2) and (3). Given any vector \( q \in \Delta_k^N \), one can use a systematic sampling scheme, such as Madow’s sampling, to efficiently sample a \( k \)-set in \( O(N) \) time such that the \( i^{th} \) element is included in the sampled set with probability \( q_i, i \in [N] \). For completeness, we briefly review Madow’s sampling scheme in Algorithm 3 in the Appendix.

Since the set of feasible inclusion probabilities \( \Delta_k^N \), given by (2) and (3), is convex, one can use the standard Online Convex Optimization framework for sequentially learning a suitable marginal inclusion probability \( p_t \in \Delta_k^N \) at every round (Hazan, 2019). The paper by Mukhopadhyay et al. (2022) uses the Follow-the-Regularized-Leader (FTRL) framework with the entropic regularizer, that computes the marginal inclusion probabilities by solving the following optimization problem:

\[
\begin{aligned}
p_t &= \arg \max_{p \in \Delta_k^N} \left[ \left( \sum_{s=1}^{t-1} g_s \right)^\top p - \frac{1}{\eta} \sum_{i=1}^{N} p_t \ln p_t \right].
\end{aligned}
\]

1. See Section 6 for the Semi-Bandit model where the coefficients of the selected components only are revealed.
The authors show that the above optimization problem can be efficiently solved in $\tilde{O}(N)$ time per round. Upon computing the marginals, one can then use Madow’s sampling scheme to sample $k$ elements without replacement corresponding to the marginal inclusion probabilities $p_t$. The overall policy is summarized in Algorithm 1. The policy enjoys the following learning guarantee.

**Algorithm 1 Online Subset Selection Policy for Linear Rewards**

Require: Sequence of linear reward functions $\{f_t\}_{t \geq 1}$ with coefficients $\{g_t\}_{t \geq 1}$, $\eta = \sqrt{\frac{k \ln(N/k)}{2G^2T}}$

1: $p_1 \leftarrow \left(\frac{k}{N}, \frac{k}{N}, \ldots, \frac{k}{N}\right)$.
2: for every round $t$:
   3:     Efficiently sample a $k$-set according to the inclusion probability vector $p_t$ using Madow’s sampling scheme given in Algorithm 3
   4:     Receive the coefficient vector $g_t$ of the linear reward function $f_t$
   5:     Compute the new inclusion probability vector $p_{t+1}$ in $\tilde{O}(N)$ time by solving the problem (4).
3: end for

**Theorem 1 (Regret bound for LINEAR-REWARDS (Mukhopadhyay et al., 2022))** The online policy in Algorithm 1 yields the following static regret bound for the LINEAR-REWARD problem:

$$\max_{p^* \in \Delta^k} \sum_{t \leq T} \langle g_t, p^* \rangle - \sum_{t \leq T} \langle g_t, p_t \rangle \leq 2G \sqrt{2kTN \ln \frac{N}{k}},$$

where the quantity $G$ upper bounds the $\ell_2$ norms of each of the coefficient vectors $\{g_t\}_{t=1}^T$.

Although we focus on the complete information setting in this paper, we can show that the same regret bound (5) holds even in the more general semi-bandit feedback model where only the chosen components of the reward vector are revealed to the learner. Please refer to Section 6 for a brief discussion on the semi-bandit model and Appendix J for details.

**Remarks:** Instead of using the entropic regularizer in (4), one can also use other strongly convex regularizers with a corresponding regret bound and run-time complexity. For example, the logarithmic factor from the regret bound (5) can be removed using a quadratic regularizer at the expense of a more computationally intense projection step. In the proposed SC\textsc{O}RE policy, we use Algorithm 1 as a subroutine to learn a broad class of non-linear reward functions described below.

3. Admissible Rewards

In this section, we define and characterize the class of admissible reward functions that can be learned by our proposed online policy SC\textsc{O}RE. In Section 5, we give several examples to show that the class of admissible rewards is sufficiently rich and includes a number of standard reward functions encountered in practice. Recall that a function $f : 2^{[N]} \rightarrow \mathbb{R}$ is monotone non-decreasing when $f(S) \leq f(T), \forall S \subseteq T$. Furthermore, we assume that all reward functions are normalized, i.e., $f_t(\emptyset) = 0, \forall t$. 

**Definition 2 (α-admissible rewards)** A non-negative reward function $f : 2^N \to \mathbb{R}_+$ is called α-admissible ($\alpha \geq 1$) if there exists a set of real numbers $g_1, g_2, \ldots, g_N$ such that

\[
\sum_{i \in S} g_i \leq \alpha f(S), \quad \forall S \subseteq [N],
\]

\[
\sum_{i=1}^N g_i = f([N]).
\]

The class of all α-admissible reward functions is denoted by $F_\alpha$. The set of all vectors $g \in \mathbb{R}^N$ satisfying (6) and (7) is called the α-core of the function $f$ and is denoted by $\text{CORE}_\alpha(f)$. For an α-admissible function $f$, any vector $g \in \text{CORE}_\alpha(f)$ is called α-admissible.

From Definition 2, it immediately follows that the class $\{F_\alpha\}_{\alpha \geq 1}$ is monotone non-decreasing, i.e., $F_{\alpha_2} \supseteq F_{\alpha_1}, \forall \alpha_2 \geq \alpha_1 \geq 1$. Linear (i.e., modular) functions are trivially 1-admissible. Curiously enough, class $F_1$ coincides with the set of all transferable-utility (TU) coalitional cost-sharing games $(N, f)$ with a non-empty Core (Shapley, 1971; Maschler et al., 2020)\(^2\). In the terminology of cooperative game theory, a 1-admissible vector is known as a *coalitionally rational imputation* for the game $(N, f)$ (Maschler et al., 2020).

To illustrate the notion of α-CORE, consider the following economic example. Assume that the team leader of a team of $N$ people is interested in having her entire team lunch together at a restaurant. The team members are willing to share the food and split the cost. The total cost for serving the whole team is $f([N])$, and the price for separately serving a subgroup of members $S \subset [N]$ is $f(S)$. Assume that the team leader proposes to split the total cost of $f([N])$ according to the vector $g$ where the $i^{th}$ person pays an amount of $g_i, i \in [N]$. Since the entire cost of $f([N])$ must be fully paid by all members together, the vector $g$ must satisfy the constraint (7). On the other hand, condition (6) ensures that no strict subgroup of the team members has an incentive to defect and eat separately by paying less than $\alpha$ times of their total payment proposed by the team leader. Interestingly, we do not require the payment vector to be component-wise non-negative. Although the notion of α-CORE has a clear economic significance (Vazirani, 2022), in this paper, we are primarily concerned with the mathematical and computational properties of α-CORE and its connection with online learning.

The question of the existence of a non-empty core for different classes of games has been extensively investigated in the cooperative game theory literature. In general, determining the non-emptiness of the core of an arbitrary game is known to be *NP-Complete* (Conitzer and Sandholm, 2003, Theorem 1). The celebrated Bondareva-Shapley theorem gives a necessary and sufficient condition for a TU coalitional game to have a non-empty core. In the following, we extend this result to the rewards class $\{F_\alpha, \alpha \geq 1\}$.

**Theorem 3 (Generalized Bondareva-Shapley Theorem)** A reward function $f : 2^N \to \mathbb{R}$ is α-admissible iff for every function $\delta : 2^N \to [0, 1]$ where $\sum_{S : i \in S} \delta(S) = 1, \forall i \in [N]$, we have

\[
\alpha \sum_{S \subseteq [N]} \delta(S)f(S) \geq f([N]).
\]

\(^2\) In the more common profit-sharing paradigm considered in the game-theoretic literature, the direction of the inequalities in (6) are reversed in the definition of Core.
We prove Theorem 3 in Appendix B by considering the dual of the LP given in Definition 2. Theorem 3 implies the following computational interpretation for the \( \alpha \text{-CORE} \). Consider an instance of the WEIGHTED SET COVER problem on the system \( ([N], 2^{|N|}) \) where the cost for selecting a subset \( S \) is defined to be \( c(S) \equiv f(S)/f([N]), S \subseteq [N] \). If the minimum cost to fractionally cover all elements in \([N]\) is \( \text{OPT}^{*} \), then the smallest value of \( \alpha \) for which \( \text{CORE}_{\alpha} (f) \) is non-empty can be upper-bounded by \( 1/\text{OPT}^{*} \). In particular, Theorem 3 implies that the \( \alpha \text{-CORE} \) of any non-negative reward function is non-empty for a large-enough \( \alpha \geq 1 \).

Finally, the following structural result shows that the \( \alpha \text{-CORE} \) of any reward function, taking values in the interval \([0, M]\), entirely lies inside the Euclidean ball of radius \( \alpha M\sqrt{2} \) centered at the origin. Surprisingly, the radius of the ball is independent of the ambient dimension \( N \). As we will see in Theorem 5, Proposition 4 is the key to our \textit{dimension-free} augmented regret bound.

Proposition 4  Let \( f \) be an \( \alpha \text{-admissible} \) reward function taking values in the interval \([0, M]\). Then for any \( g \in \text{CORE}_{\alpha} (f) \), we have \( ||g||_2 \leq \alpha M \sqrt{2} \).

See Appendix C for the proof of Proposition 4. In the particular case of monotone \( \rho \)-submodular functions, Proposition 15 in Appendix C gives a slightly tighter bound.

4. SCORE - an Online Sparse Subset Selection Policy

On a high level, the SCORE policy uses an appropriately chosen linear function with coefficient vector \( g_t \) as a proxy for each reward function \( f_t \), which is assumed to be monotone and non-negative. Then it uses Algorithm 1 as a subroutine for sampling a \( k \)-set. In particular, if the reward function \( f_t \) is \( \alpha \text{-admissible} \), the SCORE policy chooses an \( \alpha \text{-admissible} \) vector \( g_t \in \text{CORE}_{\alpha} (f_t) \) as a proxy for the reward function \( f_t \). The pseudocode for the SCORE policy is given below in Algorithm 2. The problem of computing an \( \alpha \text{-admissible} \) vector for a given reward function is discussed in Section 5.

\begin{algorithm}
\textbf{Algorithm 2} SCORE policy for \( \alpha \text{-admissible} \) rewards
\begin{algorithmic}
\Require Sequence of \( \alpha \text{-admissible} \) reward functions \( \{f_t\}_{t\geq1} \).
\State \( p_1 \leftarrow \left( \frac{k}{N}, \frac{k}{N}, \ldots, \frac{k}{N} \right) \).
\For {every round \( t \)}
\State Sample a \( k \)-set with inclusion probabilities \( p_t \) by invoking Madow’s scheme (Algorithm 3)
\State Receive the reward function \( f_t \)
\State Compute \( g_t \leftarrow \text{CORE}_{\alpha} (f_t) \)
\State Feed the vector \( g_t \) as the reward vector for round \( t \) to Algorithm 1 and compute \( p_{t+1} \)
\EndFor
\end{algorithmic}
\end{algorithm}

Theorem 5 (Learning guarantee) Let each of the reward functions \( \{f_t\}_{t\geq1} \) be \( \alpha \text{-admissible}, \) non-negative and bounded above by \( M \). The SCORE policy given in Algorithm 2 achieves the following learning guarantee:

\[ \frac{k}{N \alpha} \sum_{t=1}^{T} f_t([N]) - \sum_{t=1}^{T} \mathbb{E}[f_t(S_t)] \leq 4M \sqrt{k T \ln \frac{N}{k}} \tag{8} \]

The LHS of the above bound is called \( \alpha \text{-augmented} \) regret.
Proof From the static regret upper bound given by Theorem 1, we have:

$$\max_{p^* \in \Delta^k_N} \sum_{t=1}^{T} \langle g_t, p^* \rangle - \sum_{t=1}^{T} \langle g_t, p_t \rangle \leq 2G \sqrt{2kT \ln \frac{N}{k}},$$  

(9)

where $p_t$ denotes the inclusion probability vector on round $t$ and $G$ is a uniform upper bound to the $\ell_2$-norms of the vectors $\{g_t\}_{t=1}^{T}$. Since each of the reward functions $\{f_t\}_{t=1}^{T}$ is assumed to be $\alpha$-admissible, and $g_t$ is chosen to be an $\alpha$-admissible vector, using Proposition 4, we can set $G := \alpha M \sqrt{2}$. Furthermore, from the defining property (6) and (7) of the $\alpha$-CORE, we have:

$$\mathbb{E}[f_t(S_t)] \geq \frac{1}{\alpha} \mathbb{E}\left[\sum_{i \in S} g_{t,i} 1(i \in S_t)\right] = \frac{1}{\alpha} \langle g_t, p_t \rangle, \quad \forall 1 \leq t \leq T,$$

(10)

and

$$f_t([N]) = \sum_{i \in [N]} g_{t,i}, \quad \forall 1 \leq t \leq T.$$

Hence,

$$\sum_{t=1}^{T} f_t([N]) = \sum_{i \in [N]} \sum_{t=1}^{T} g_{t,i} \overset{(a)}{\leq} \frac{N}{k} \max_{p^* \in \Delta^k_N} \sum_{t=1}^{T} \langle g_t, p^* \rangle,$$

(11)

where in inequality (a), we have used the fact that the maximum value of a set of real numbers is lower bounded by their average value. Finally, upon combining the bounds (9), (10), and (11), we get the following upper bound on the augmented regret achieved by the SCORE policy:

$$\frac{k}{N\alpha} \sum_{t=1}^{T} f_t([N]) - \sum_{t=1}^{T} \mathbb{E}[f_t(S_t)] \leq 4M \sqrt{kT \ln \frac{N}{k}}.$$

Discussion: A few words on the offline benchmark, given by the first term in the augmented regret bound (8), are in order. Recall that, in the definition of the standard static regret, the offline benchmark is taken to be the cumulative reward accrued by the optimal fixed action in hindsight (Zinkevich, 2003). Consequently, this benchmark could be weak if the reward functions change drastically over time. In order to address this fundamental issue, different variants of the regret metric, such as adaptive regret (Mokhtari et al., 2016) and dynamic regret (Hazan and Seshadhri, 2009), have been proposed, which allows some temporal variability in the offline benchmark. On the other hand, in the augmented regret bound (8), the offline benchmark is taken to be a fraction $\eta \equiv k/N\alpha$ of the maximum cumulative reward obtained by an omnipotent algorithm that could select all $N$ elements at all times, thus bypassing the issue discussed above. The inverse relationship between $\eta$ and $\alpha$ signifies the hardness (either information-theoretic or computational) for learning the given sequence of reward functions. In particular, to obtain a tighter augmented regret bound, we would like the parameter $\alpha$ to be as close to unity as possible. However, a specific sequence of reward functions might not be $\alpha$-admissible for small values of $\alpha$. Furthermore, even if the reward
functions are known to be $\alpha$-admissible, finding an $\alpha$-admissible vector could be computationally intractable. The reader is referred to Section 5 for a detailed discussion and examples. Finally, we emphasize that the learning guarantee given in Theorem 5 is incomparable with the existing static regret guarantees in the literature (Streeter and Golovin, 2007). The following result gives a basic lower bound that shows that the worst-case augmented regret of any online policy is non-negative.

**Theorem 6 (Lower bound on Augmented Regret)** For any (randomized) online subset selection policy $\pi$, there exists a sequence of monotone non-negative linear (and hence, $1$-admissible) reward functions $\{f_t\}_{t \geq 1}$ such that its $1$-augmented regret is non-negative, i.e.,

$$\frac{k}{N} \sum_{t=1}^{T} f_t([N]) - \sum_{t=1}^{T} E_{\pi} f_t(S_t) \geq 0$$

(12)

The proof uses a probabilistic argument. See Appendix D for the proof of Theorem 6.

5. Examples of Admissible Rewards

In this section, we give several examples of admissible reward functions that often arise in practice. Since the only non-trivial part of the SCORE policy is the computation of an $\alpha$-admissible vector for some $\alpha \geq 1$, we focus exclusively on this problem in this section.

5.1. Submodular Rewards

Informally speaking, submodular functions are set functions that have the *diminishing return* property as formalized below.

**Definition 7 (Submodular function)** A function $f : 2^{[N]} \rightarrow \mathbb{R}$ is called submodular if $\forall B \subseteq [N], A \subseteq B, i \in B^c$:

$$f(B \cup \{i\}) - f(B) \leq f(A \cup \{i\}) - f(A).$$

(13)

**Examples:** Many objective functions arising in the field of machine learning and artificial intelligence are known to be submodular. See Bilmes (2022) for a recent survey. In the following, we give only some representative examples.

1. Let $X = (X_1, X_2, \ldots, X_N)$ be a random vector. Then the Entropy function $H(X_S)$ and the mutual information function $I(X_S; X_{S^c})$ are known to be monotone submodular.

2. Consider a social network represented by a graph $G(V, E)$, all of whose nodes are initially in the inactive state. For a subset $S \subseteq V$, define the influence function $\sigma(S)$ to be the expected number of active nodes at the end of an influence spread process where the subset $S$ was activated at the beginning. In a pioneering paper, Kempe et al. (2003, Theorem 2.2, Theorem 2.5) showed that under two standard influence spread processes (Independent Cascade and Linear Threshold), the influence function $\sigma(\cdot)$ is monotone submodular.

3. Given a family of sets $\{U_v\}_{v \in V}$, the coverage function defined as $\text{COVER}(S) := |\cup_{i \in S} U_i|, S \subseteq V$ is monotone submodular.
The following result shows that the SCORE policy can efficiently learn the class of submodular functions.

**Theorem 8 (Shapley, 1971)** Submodular functions are 1-admissible. Furthermore, for any permutation \( \pi : [N] \to [N] \), define the marginal utility vector as \( \Delta^\pi_{\pi(i)} \equiv f(\pi(1), \pi(2), \ldots, \pi(i)) - f(\pi(1), \pi(2), \ldots, \pi(i - 1)), \forall i \in [N] \). Then \( \Delta^\pi \in \text{CORE}_1(f) \).

Theorem 8 is a well-known result in cooperative game theory. We prove a generalized version of this theorem in Appendix F. The above results imply that many practical online subset selection problems with cardinality constraints, including the online version of the sensor placement problem (Guestrin et al., 2005) and the influence maximization problem in social networks with targeted interventions (Kempe et al., 2003) can be efficiently solved using SCORE. The following examples give more nuanced applications of the SCORE policy.

**Example 1 (Budgeted Assignment (Golovin et al., 2009))** Assume that there are \( N \) webpages, denoted by the set \([N]\), where one may buy ad spaces for displaying ads. However, due to budget constraints, we can afford to buy ad spaces in only a subset \( S \subseteq [N] \) of \( k \) webpages. If page \( i \) is selected for advertising, we may choose to display any one ad from the pool of ads \( P_i, i \in [N] \). Let \( \Pi = (p_1, p_2, \ldots, p_N) \) be an assignment which assigns an ad \( p_i \in P_i \) to each page \( i \). The reward (e.g., the cumulative click-through rate) for the choice of webpages \( S \) and the ad assignment \( \Pi \) is given by the function \( f(S, \Pi) \). For a fixed assignment \( \Pi \), the reward function \( f(\cdot, \Pi) \) is typically assumed to be monotone and submodular, and thus 1-admissible by Theorem 8. Hence, Theorem 5 implies that a sequence of reward functions \( \{f_t(\cdot, \Pi)\}_{t \geq 1} \) can be efficiently learned by the SCORE policy. In ad exchanges, one is typically interested to learn both the optimal subset of pages \( S^*(|S^*| = k) \) to put ads on and the optimal assignment of ads \( \Pi^* \) to pages. Similar problems arise in news recommendations and sponsored searches. In Appendix E, we show how this more general problem can be efficiently solved by the SCORE policy.

**5.2. White-box access to combinatorial rewards**

Given black-box oracle access to a submodular function, Theorem 8 gives an efficient method to compute a 1-admissible vector. However, in many problems, the reward function is naturally defined as a solution to a non-trivial combinatorial optimization problem. Hence, invoking the evaluation oracle could be prohibitively expensive for these problems. Instead, the learner is provided access to the underlying combinatorial object itself (e.g., the graph). The following example, adapted from the classic paper by Shapley and Shubik (1971), shows that a 1-admissible vector for the Minimum-Cost Bipartite Matching problem can be computed efficiently.

**Example 2 (Minimum-Cost Bipartite Matching)** Consider a non-negative weighted complete bipartite graph \( G(U, V, E, w) \), where the cost of the edge \((u, v) \in E \) is \( w_{uv} \). Let \( k \leq 2|U| \) be an even integer. For any subset of vertices \( S_U \subseteq U, S_V \subseteq V \) consisting of \( k/2 \) elements each, let the value of the reward function \( f(S_U \cup S_V) \) be given by the weight of the minimum cost perfect matching on the subgraph induced by the vertices \( S \equiv S_U \cup S_V \). Using ideas from bipartite matching and duality theory, in Appendix G, we show that the above reward function is 1-admissible. Furthermore, a 1-admissible vector can be efficiently computed from the optimal solution to the dual of the Minimum Cost Matching LP.
ON LINE SUBSET USE IN ELECTION USING $\alpha$-CORE WITH NO AUGMENTED REGRET

Note: The above reward function arises in a two-player zero-sum game where the first player chooses two subsets $S_U \subseteq U$ and $S_V \subseteq V$ s.t. $|S_U| = |S_V| = k/2$. Upon observing the first player’s choice, the second player chooses a perfect matching on the selected vertices and incurs a cost equal to the price of the matching. Hence, for any choice of the subsets, the reward obtained by the first player is equal to the cost of the minimum cost perfect matching on the selected vertices.

5.3. Non-Submodular Rewards and Shapley Value

If the reward function is not submodular, the marginal utility vector $\Delta^\pi$ for a given permutation $\pi$, defined in Theorem 8, might not lie in the core even if the core is non-empty. Fortunately, for some reward functions satisfying certain conditions, the Shapley value of the reward function, defined below, is guaranteed to be included in the core.

Definition 9 (Shapley value) The Shapley value $Sh_i(f)$ is defined as $Sh_i(f) = \mathbb{E} \Delta^\pi_i, \forall i \in [N]$ where the expectation is over all permutations on $[N]$ taken uniformly at random.

Shapley value exists for any reward function. Although the problem of computing the Shapley value for arbitrary reward functions is NP-Hard, efficient quasi-Monte Carlo algorithms for estimating the Shapley value exist (Mitchell et al., 2022). Obviously, showing that the Shapley value is in the core is sufficient to prove the non-emptiness of the core (and hence, the 1-admissibility of the reward function). Towards this, we recall the following result.

Theorem 10 (Izawa and Takahashi, 1998) The Shapley value of a function $f$ is included in the core if and only if for all $T \subseteq [N]$, the following holds

$$
\sum_{S \subseteq [N]} \sum_{i \in S \cap T} \frac{(|S| - 1)!(N - |S|)!}{N!}[f_i(S) - f_i(S \cap T)] \leq 0,
$$

where $f_i(S) \equiv f(S) - f(S \setminus \{i\})$ is the marginal contribution of the $i^{th}$ element to the set $S \ni i$.

As an application of the above result, recall that a reward function $f$ is called average submodular if the diminishing return property (13) holds on the average, i.e., $\forall A, B \neq \emptyset, A \cap B = \emptyset$

$$f(A \cup B) - f(B) \leq \frac{1}{|B|} \sum_{i \in B} [f(A \cup (B \setminus \{i\})) - f(B \setminus \{i\})].$$

Theorem 10 implies that average submodular functions have a non-empty core, and the Shapley value is in the core (Sprumont, 1990). Note that average submodular functions need not be submodular (Iñarra and Usategui, 1993).

5.4. Non-Submodular Rewards and $\alpha$-admissibility

So far, we have considered reward functions that are 1-admissible. In this section, we discuss some non-submodular function classes that can be shown to be $\alpha$-admissible for some $\alpha \geq 1$. First, we introduce the notion of a dictator element.

Definition 11 ($m$-dictator) For some $m > 0$, assume that there exists an element $i^* \in [N]$ s.t. $f(U) \geq m, \forall U \ni i^*$. Then we call the element $i^*$ to be an $m$-dictator.
If the reward function \( f \) is monotone, the condition \( \max_i f(\{i\}) \geq m \) is sufficient for the existence of an \( m \)-dictator. The set covering interpretation of the \( \alpha \)-CORE, given in Section 3, readily yields the following sufficient condition for the \( \alpha \)-admissibility of a reward function in terms of the existence of a dictator element.

**Proposition 12** Any reward function, taking values in the interval \([0, M]\) and containing an \( m \)-dictator, is \( \frac{M}{m} \)-admissible.

**Proof** The proof follows immediately from the dual characterization given in Theorem 3. If the element \( i^* \) is an \( m \)-dictator, we have

\[
\frac{M}{m} \sum_{S \subseteq [N]} \delta_S f(S) \geq \frac{M}{m} \sum_{U : i^* \in U} \delta_U f(U) \geq \frac{M}{m} \sum_{U : i^* \in U} m \delta_U = M \sum_{U : i^* \in U} \delta_U = M \geq f([N]),
\]

where (a) follows from the fact that the element \( i^* \) is an \( m \)-dictator and (b) follows from the fact that \( \delta \) covers the element \( i^* \).

In Section H of the Appendix, we show how to efficiently construct an \( M/m \)-admissible vector when the reward function contains an \( m \)-dictator. Note that although the bound given by Proposition 12 might be loose, it is widely applicable as it does not assume any particular structure of the reward function. In the following, we apply Proposition 12 to the problem of sparse linear regression.

As shown in (Altschuler et al., 2016, Remark 1), the reward function \( f(\cdot) \) defined below is not submodular or even sub-additive.

**Example 3 (Sparse Linear Regression (Khanna et al., 2017))** Consider the problem of sparse linear regression:

\[
\min_{\beta} \|y - X\beta\|_2^2 \quad \text{s.t.} \quad \|eta\|_0 \leq k, \tag{14}
\]

where \( X \in \mathbb{R}^{n \times d}, d \geq n \) is a given feature matrix with unit-norm columns, and \( y \in \mathbb{R}^n \) is a response vector having unit Euclidean norm. Assume that \( X \) is full rank. It is well-known that for fixed support set \( S \), the optimal regressor coefficient is given by \( \beta_S^* = (X_S^T X_S)^{-1} X_S^T y \), where \( X_S \) is the sub-matrix formed by choosing columns of \( X \) corresponding to the subset \( S \). Hence, the Pythagorean theorem implies that Problem 14 is equivalent to maximizing the following reward function subject to the cardinality constraint on \( S \):

\[
f(S) = \|\Pi_S y\|_2^2,
\]

where \( \Pi_S = X_S(X_S^T X_S)^{-1} X_S^T \) is the projection matrix that projects any vector onto the column span of the matrix \( X_S \). Clearly, \( 0 \leq f(S) \leq 1, \forall S \subseteq [N] \). In Appendix I, we show that \( f(\cdot) \) contains an \( \frac{\sigma_{\min}(X)}{d} \)-dictator, and hence, by Proposition 12, the reward function is \( \frac{\sigma_{\min}(X)}{d} \)-admissible.

An important class of approximately submodular functions is the class of \( \rho \)-submodular functions (El Halabi et al., 2018a; Sakaue, 2019). For these functions, the diminishing return property of submodular functions (13) holds approximately up to a factor of \( \rho > 0 \). Formally, a \( \rho \)-submodular function is defined as follows.
Definition 13 ($\rho$-submodularity (El Halabi et al., 2018a)) A function $f : 2^{[N]} \to \mathbb{R}$ is $\rho$-submodular iff $\exists \rho \in (0, 1]$ s.t. $\forall B \subseteq [N], A \subseteq B, i \in B^c$:

$$\rho(f(B \cup \{i\}) - f(B)) \leq f(A \cup \{i\}) - f(A).$$

Clearly, a $\rho$-submodular function $f$ is submodular if and only if $\rho = 1$. The paper by El Halabi et al. (2018a, Proposition 2) gives a necessary and sufficient condition for a finite-valued monotone function to be $\rho$-submodular. In particular, their result implies that any finite-valued strictly monotone function is $\rho$-submodular for some $\rho > 0$. The following theorem gives a sufficient condition for the admissibility of $\rho$-submodular functions.

Theorem 14 A $\rho$-submodular function $f$ is $1/\rho$-admissible. Furthermore, the marginal utility vector $\Delta^\pi$, defined in Theorem 8, is $1/\rho$-admissible. Note that the vector $\Delta^\pi$ can be efficiently computed without knowing the value of the parameter $\rho$.

See Appendix F for the proof. Theorem 14 implies that for the class of $\rho$-submodular functions, the SCORE policy can be run without knowing the value of the parameter $\rho$. Hence, we can automatically ensure the optimal augmented regret-bound (8) with the largest possible value of $\rho$ for the given sequence of approximately submodular reward functions. The following example shows an application of $\rho$-submodularity in a Bayesian Optimization setting.

Example 4 (Batch Bayesian Optimization (El Halabi and Jegelka (2020))) Consider the Bayesian optimization problem in a batch setting where the goal is to optimize an unknown expensive-to-evaluate function $f$ with a small number of noisy evaluations. Consider the following additive noisy observation model:

$$y = f(x) + \epsilon,$$

where the unknown function $f$ is modeled using a Gaussian process (GP) with kernel $k(x, x')$ and $\epsilon \overset{i.i.d.}{\sim} \mathcal{N}(0, \sigma^2)$. Given a set of potential optimizers $X = \{x_1, \cdots, x_N\}$, and $S \subseteq [N]$, the posterior distribution of $f$, given observations $Y_S$ on the selected points $\{x_i, i \in S\}$ is again a Gaussian process with variance $\sigma^2_S(x) = k(x, x) - k(x)^\top (K_S + \sigma^2 I)^{-1} k(x)$, where $k(x) = \{k(x_i, x)\}_{i \in S}$ and $K_S = \{k(x_i, x_j)\}_{i,j \in S}$ are the corresponding sub-matrices of the kernel matrix $K$. The variance reduction function, a widely-used acquisition function, is defined as follows (Bogunovic et al., 2016):

$$G(S) = \sum_{i \in [N]} (k(x_i, x_i) - \sigma^2_S(x_i)).$$

El Halabi and Jegelka (2020) showed that the set function $G$ is $\rho$-submodular s.t.

$$\rho \geq \left( \frac{\lambda_{\min}(K)}{\lambda_{\min}(K) + \sigma^2} \right)^2 \frac{\lambda_{\min}(K)}{\lambda_{\max}(K)} : = \eta,$$

where $\lambda_{\max}(K)$ and $\lambda_{\min}(K)$ are the maximum and minimum eigenvalues of $K$, respectively. Hence, it follows from Theorem 14 that $G$ is $\eta^{-1}$ admissible. Therefore, the SCORE policy can learn a sequence of unknown functions modeled as a GP with time-varying kernel matrices.
6. Semi-Bandit Feedback

Recall that Algorithm 1 assumes the full-information model where, irrespective of its decision, all components of the reward vector \( g_t \) are revealed to the learner at the end of round \( t \). Under the semi-bandit feedback model, only the selected \( k \) elements of the reward vector (i.e., \( \{ g_{t,i}, i \in S_t \} \)) are revealed to the learner on round \( t \) (Kale et al., 2010). We show in Appendix J that for linear rewards, one can use the standard inverse propensity scoring rules to estimate the unseen components and extend Algorithm 1 efficiently to the adversarial semi-bandit setting (Hazan, 2019). In the case of non-linear reward functions \( f_t \), observe that the SCORE policy only needs to have access to an \( \alpha \)-admissible vector \( g_t \in \text{CORE}_\alpha (f_t) \). In the semi-bandit setting, we assume that the learner can access the \( k \) selected components of an \( \alpha \)-admissible vector \( g_t \) at round \( t \) only. Our feedback model subsumes the model used by Takemori et al. (2020), where the learner observes the marginal gains for the chosen items for submodular reward functions. In Appendix J, we show that the policy enjoys a \( O(\sqrt{T}) \) static regret guarantee under the semi-bandit feedback setting for linear rewards.

7. Related Works

In this section, we briefly review some papers related to the subset selection problem.

7.1. Online Set Function Maximization

Most of the previous works in online set function maximization have been restricted to the case when the reward functions are submodular. Numerous works have studied online submodular maximization problems since the seminal paper by Streeter and Golovin (2008), which greedily runs \( k \) expert policies at every round to sample a set of \( k \) elements. Roughgarden and Wang (2018) studied the non-monotone submodular optimization problem and provided an online double greedy strategy that achieves a \( \frac{1}{2} \)-approximate regret bound. Recently, Harvey et al. (2020) improved the static regret bounds for both problems. Furthermore, both problems have been explored with the notion of tracking regret by Matsuoka et al. (2021). The study of online non-submodular set function maximization has been driven by the online sparse linear regression problem (Foster et al., 2016; Kale et al., 2017). Kale et al. (2017) provided an efficient algorithm for the problem in the adversarial setting by leveraging the greedy strategy proposed by Streeter and Golovin (2008) and incorporating weak submodularity (Boutsidis et al., 2015) in their utility set functions. The subset-selection problem for linear reward functions arises in online caching, which has been recently studied by Bhattacharjee et al. (2020); Paschos et al. (2019); Paria and Sinha (2021).

7.2. Weak Submodularity

In many real-world problems ensuring utility functions are submodular can be pretty restrictive. For example, the problems of dictionary selection (Cevher and Krause, 2011) and column subset selection (Boutsidis et al., 2009; Altschuler et al., 2016) are known to have non-submodular utility functions. To address this issue, several works have considered different notions of weak submodularity. The idea of submodularity ratio and, consequently, weak submodularity was introduced by Das and Kempe (2011) in the context of the subset selection problem. The concept of weak submodularity has also been studied by relaxing the notion of decreasing marginal gains by a factor of \( \gamma \in [0, 1] \) under names such as inverse curvature (Bogunovic et al., 2018), DR ratio (Kuhnle et al., 2018) and generic submodularity ratio (Nong et al., 2019). Santiago and Yoshida (2020) extended
the notion of weak submodularity for non-monotone functions and introduced the notion of local submodularity ratio. El Halabi et al. (2018b) introduced the notion of $p$-submodularity, and El Halabi and Jegelka (2020) introduced the notion of weak diminishing return (DR) submodularity, both of which are closely related to weak submodularity and have been frequently employed in the recent literature on non-submodular optimization. Recently, Thiery and Ward (2022) further refined the concept of the submodularity ratio defined by Das and Kempe (2011) for monotone functions which they term as two-sided weak submodularity.

7.3. Approximate Core in Cooperative Game Theory

Shapley (1971) proved that convex games (i.e., games with a submodular cost function) have non-empty cores. However, the core of a cooperative game could be empty for many interesting classes of reward functions (Maschler et al., 2020). Various approximations of the core have been introduced to overcome this problem. These approximations of the core can be either additive or multiplicative. Examples of additive approximations to the core of cooperative games are least core (Maschler et al., 1979) or nucleolus (Schmeidler, 1969). Recently, Vazirani (2022) provided an $\alpha$-multiplicative approximation of the core in the context of a general graph matching game for $\alpha = 2/3$. Similarly, Munagala et al. (2022) proposed a multiplicative approximation of the core for the committee selection problem.

8. Concluding Remarks and Open Problems

In this paper, we designed an efficient online subset selection policy called SCORE for a broad class of reward functions in the complete information and semi-bandit feedback model. The SCORE policy uses the concept of an approximate core from the cooperative game theory literature to obtain modular approximations to the reward functions and guarantees $O(\sqrt{T})$ $\alpha$-augmented-regret. An interesting open problem is to extend the SCORE policy to the bandit feedback setting, where only the reward value for the selected subset is revealed to the learner at the end of each round. Secondly, it will be interesting to investigate the subset selection problem in the setting when additional information in the form of prediction or advice is available to the learner before decisions are made on each round (Bhaskara et al., 2020). Thirdly, our lower bound is pretty basic. It would be interesting to establish a lower bound on the $\alpha$-regret that either matches the upper-bound or shows a non-trivial dependence on the horizon-length for a class of reward functions. Finally, it would be nice to systematically characterize the trade-off between the computational complexity of finding an $\alpha$-admissible vector as a function of the approximation parameter $\alpha$ for a class of reward functions.
References

Appendix A. Madow’s Sampling Algorithm

The following pseudocode outlines Madow’s algorithm, which randomly samples a subset of \( k \) elements without replacement from a universe of \( N \) elements such that each element \( i \in [N] \) is included in the sample with a pre-specified probability \( p_i, i \in [N] \). The marginal inclusion probabilities are assumed to satisfy conditions (2) and (3).

Algorithm 3 Madow’s Sampling Scheme

Require: A universe \([N]\) of size \( N \), the cardinality of the sampled set \( k \), and a marginal inclusion probability vector \( p = (p_1, p_2, \ldots, p_N) \) satisfying conditions (2) and (3).

Ensure: A random \( k \)-set \( S \) with \(|S| = k \) such that \( P(i \in S) = p_i, \forall i \in [N] \)

1: Define \( \Pi_0 = 0 \), and \( \Pi_i = \Pi_{i-1} + p_i, \forall 1 \leq i \leq N \).
2: Sample a uniformly distributed random variable \( U \) from the interval \([0, 1]\).
3: \( S \leftarrow \emptyset \)
4: for \( i \leftarrow 0 \) to \( k - 1 \) do
5: \( \) Select the element \( j \) if \( \Pi_{j-1} \leq U + i < \Pi_j \).
6: \( S \leftarrow S \cup \{j\} \).
7: end for
8: return \( S \)

Correctness: It can be easily argued that Madow’s sampling procedure, described in Algorithm 3, outputs a random set \( S, |S| = k \), such that \( P(j \in S) = p_j, \forall j \in [N] \). To see this, note that by the feasibility condition of the inclusion probabilities, we have \( \Pi_N = k \). Hence, Algorithm 3 samples exactly \( k \) elements. Furthermore, for any realization of the uniform r.v. \( U \), there exists a unique integer \( i^*_j \) such that \( \Pi_{j-1} \leq U + i^*_j \leq \Pi_j \). Hence,

\[
P(j \in S) = P(\Pi_{j-1} \leq U + i^*_j \leq \Pi_j) = \Pi_j - \Pi_{j-1} = p_j, \forall j \in [N].
\]

Appendix B. Proof of Theorem 3

Proof Consider the following LP, which corresponds to \( \text{CORE}_\alpha(f) \).

\[
\mathcal{P}:
\]

maximize \( 0 \)

subject to

\[
\sum_{i \in S} g_i \leq \alpha f(S), \forall S \subseteq [N], \quad (15)
\]

\[
\sum_{i \in [N]} g_i = f([N]). \quad (16)
\]

Associating a dual variable \( \delta_S \) to each constraint in (15) and a dual variable \( \mu \) to the constraint (16), we can write down the dual \( \mathcal{D} \) to the LP \( \mathcal{P} \) as follows (Bertsimas and Tsitsiklis, 1997).

\[
\mathcal{D}:
\]
\[
\text{minimize } \alpha \sum_{S \subseteq [N]} \delta_S f(S) + \mu f([N])
\]

subject to
\[
\sum_{S : i \in S} \delta_S + \mu = 0, \forall i \in S,
\]
\[
\delta_S \geq 0, \forall S \subseteq [N].
\]

It can be seen that the dual \( D \) is feasible, and its optimal value is upper-bounded by 0 (take, e.g., the feasible solution \( \delta_S = 0, \forall S \subseteq [N], \) and \( \mu = 0 \). Hence, from the Strong duality theorem, \( \text{CORE}_\alpha (f) \) is non-empty if and only if the objective value of the dual \( D \) is non-negative for all dual feasible solutions. In other words,
\[
\text{CORE}_\alpha (f) \neq \emptyset \iff \alpha \sum_{S \subseteq [N]} \delta_S f(S) - \mu f([N]) \geq 0 \forall \delta, \mu \text{ satisfying (18) and (19)}.
\]

where the last equivalence follows from the fact that \( f \) is non-negative, and hence, it is sufficient to check the inequality for strictly negative \( \mu \) only. Finally, rescaling the variables \( \delta_S \leftarrow \frac{\delta_S}{\mu}, \forall S \subseteq [N], \) we conclude that
\[
\text{CORE}_\alpha (f) \neq \emptyset \iff \alpha \sum_{S \subseteq [N]} \delta_S f(S) \geq f([N])
\]

for any set of variables \( \delta \) satisfying
\[
\sum_{S : i \in S} \delta_S = 1, \forall i \in S
\]
\[
\delta_S \geq 0, \forall S \subseteq [N].
\]

This proves Theorem 3.

Appendix C. Proof of Proposition 4

Proof Using the definition of \( \alpha \)-CORE and the fact that \( g \in \text{CORE}_\alpha (f) \), we have:
\[
g_i \leq \alpha f(\{i\}) \leq \alpha M, \forall i \in [N].
\]

Similarly, we have
\[
\sum_{j \in [N] \setminus \{i\}} g_j \leq \alpha f([N] \setminus \{i\}) \leq \alpha M.
\]
Using (23) and the definition of $\alpha$-CORE again, we can write
\[
\alpha M + g_i \geq g_i + \sum_{j \in [N] \setminus \{i\}} g_j = f([N]) \geq 0.
\]  
(24)

Combining (22) and (24), we have the following upper bound for the absolute value of each component of the vector $g$:
\[
|g_i| \leq \alpha M, \quad \forall i \in [N].
\]  
(25)

Now define the index sets $P$ and $N$ as $P = \{i : g_i \geq 0\}$ and $N = \{i : g_i < 0\}$. Using the definition of $\alpha$-CORE again, we have:
\[
\sum_{i \in P} g_i \leq \alpha M.
\]  
(26)

Similarly,
\[
\alpha M + \sum_{i \in N} g_i \geq \sum_{i \in P} g_i + \sum_{j \in N} g_j = f([N]) \geq 0.
\]

This yields
\[
\sum_{j \in N} g_j \geq -\alpha M.
\]  
(27)

Finally,
\[
G^2 \leq \|g\|^2_2 = \sum_{i \in P} g_i^2 + \sum_{j \in N} g_j^2
\]
\[
(a) \leq \alpha M \sum_{i \in P} g_i - \alpha M \sum_{j \in N} g_j
\]
\[
(b) \leq 2\alpha^2 M^2,
\]
where (a) follows from (25), and the definition of the index sets $P$ and $N$ and (b) follows from (26) and (27).

**Proposition 15**  Consider a monotone $\rho$-submodular reward function $f$ taking values in the interval $[0, M]$. Then, $\exists g = (g_1, g_2, \ldots, g_N) \in \text{CORE}_{\rho-1}(f)$ such that $\|g\|_2 \leq M$.

**Proof**  Take $g$ to be the same vector as given in Theorem 14, i.e.,
\[
g_i := f(\{1, 2, \ldots, i\}) - f(\{1, 2, \ldots, i-1\}), \quad \forall i \in [N].
\]
It has been shown in Theorem 14 that $g \in \text{CORE}_\alpha(f)$. Furthermore, notice that $g_i \geq 0, \forall i \in [N]$ as $f$ is monotone. Hence, we have
\[
\|g\|^2_2 \leq \|g\|^2_1 = \left(\sum_{i=1}^N g_i\right)^2 = f^2([N]) \leq M^2.
\]

Appendix D. Proof of Theorem 6

We construct a $T \times N$ random matrix $r$ with independent rows such that each row contains exactly one 1 corresponding to a column chosen uniformly at random from the set of all $N$ columns, and the rest of the $N - 1$ entries in that row are zero. To put it formally, let $\{I_t\}_{t=1}^T$ be a sequence of i.i.d. random variables s.t. $I_t \sim \text{Unif}([N]), \forall t$. We define the $(t,i)^{th}$ entry of the matrix to be

$$r_{t,i} = \mathbb{1}(t = I_t), \forall t, i.$$

Now consider a random ensemble of sequence of linear reward functions $\{f_t\}_{t=1}^T$ defined as $f_t(S) = \sum_{i \in S} r_{t,i}, \forall S \subseteq [N]$. Clearly, by construction $f_t([N]) = 1, \forall t \geq 1$. Now recall that any online subset selection policy chooses (perhaps randomly) $k$ elements out of $N$-elements at every round. Thus the r.v. $f_t(S_t)$ is Bernoulli with $\mathbb{E}(f_t(S_t)) = k/N$. Hence, using the linearity of expectation, the expected value of the augmented regret over the random ensemble can be computed as:

$$\mathbb{E} \left[ \frac{k}{N} \sum_{t=1}^T f_t([N]) - \sum_{t=1}^T f_t(S_t) \right] = \frac{kT}{N} - \frac{kT}{N} = 0.$$

This implies that for every online subset selection policy $\pi$, there exists a sequence of linear reward functions $\{f_t\}_{t=1}^T$ such that the augmented regret achieved by the policy $\pi$ is non-negative.

Appendix E. The BUDGETED ASSIGNMENT PROBLEM

The paper by Golovin et al. (2009) considers a particular case of the online assignment problem, discussed in Example 1, with no budget constraints. In this problem, one may place ads on all of the $N$ webpages (i.e., $k = N$). Let $A$ denote the set of all assignments of ads to webpages. Given a sequence of reward functions $\{f_t([N], \cdot)\}_{t \geq 1}$, their proposed online assignment policy, called TGBANDIT, selects a series of assignments $\{G_t\}_{t \geq 1}$, achieving the following $(1 - 1/e)$ regret guarantee:

$$\mathbb{E} \left[ \sum_{t=1}^T f_t([N], G_t) \right] \geq (1 - \frac{1}{e}) \max_{G \in A} \left[ \sum_{t=1}^T f_t([N], G) \right] - \tilde{O}(N^{3/2}T^{1/4}\sqrt{\text{OPT}}), \quad (28)$$

where $\text{OPT} \equiv \max_{G \in A} \sum_{t=1}^T f_t([N], G)$ is the cumulative reward accrued by the optimal static assignment. We can now combine the SCORE and TGBANDIT policy to solve the BUDGETED ASSIGNMENT PROBLEM for an arbitrary budget constraint, where only $k$ of the $N$ webpages may be selected for advertisements. Our proposed policy is described in Algorithm 4 below.

Algorithm 4 Online policy for the BUDGETED ASSIGNMENT PROBLEM

1: for every round $t$: do
2: \hspace{10pt} $G_t \leftarrow \text{TGBANDIT}$ \hspace{10pt} // Selects an assignment on all $N$ webpages
3: \hspace{10pt} $S_t \leftarrow \text{SCORE}$ \hspace{10pt} // Selects a subset of $k$ pages
4: \hspace{10pt} Feed the reward function $f_t([N], \cdot)$ to TGBANDIT
5: \hspace{10pt} Feed the reward function $f_t(\cdot, G_t)$ to SCORE
6: end for
Algorithm 4 runs an independent instance of the TGBANDIT policy, which determines a sequence of ad assignments for all $N$ webpages on all rounds. Hence, the run of the TGBANDIT policy is not affected by the concurrently running SCORE policy. On the other hand, the reward inputs to the SCORE policy is modulated with the choice of assignment made by the TGBANDIT policy.

**Analysis:** From the augmented regret guarantee (8) achieved by the SCORE policy, we have

$$
\mathbb{E}\left[\sum_{t=1}^{T} f_t(S_t, G_t)\right] \geq \frac{k}{N} \sum_{t=1}^{T} f_t([N], G_t) - \tilde{\Theta}(\sqrt{kT}).
$$

Combining (28) and (29), we have the following learning guarantee for Algorithm 4:

$$
\mathbb{E}\left[\sum_{t=1}^{T} f_t(S_t, G_t)\right] \geq (1 - \frac{1}{e}) \frac{k}{N} \text{OPT} - \tilde{\Theta}(kN^{1/2}T^{1/4}\sqrt{\text{OPT}} + \sqrt{kT}),
$$

where we recall $\text{OPT} \equiv \max_{G \in A} \left[\sum_{t=1}^{T} f_t([N], G)\right]$ is the maximum cumulative reward accrued by the best static offline assignment when ads are displayed on all $N$ webpages. It is worth pointing out that Algorithm 4 and its analysis critically exploit that SCORE policy has a sublinear augmented regret. The webpage selection algorithm and its analysis would have been much more complex had we used a subset selection policy with a static regret guarantee only (e.g., Streeter and Golovin (2008)).

**Appendix F. Proof of Theorem 14**

Let $x$ be the marginal utility vector $\Delta^\pi$ corresponding to some permutation $\pi$. Relabelling the elements as $\pi(i) \leftarrow i, \forall i \in [N]$, the components of the vector $x$ is given as follows:

$$
\begin{align*}
x_1 &= f(\{1\}), \\
x_2 &= f(\{1, 2\}) - f(\{1\}), \\
&\vdots \\
x_n &= f(\{1, 2, \cdots, n\}) - f(\{1, 2, \cdots, n-1\}).
\end{align*}
$$

Then it immediately follows that $\sum_{i \in N} x_i = f(N)$. Now, consider any set $S = \{i_1, i_2, \cdots, i_k\}$ of size $k$ such that $1 \leq i_1 < i_2 < \cdots < i_k \leq n$. Then, we have,

$$
\sum_{j \in S} x_j = \sum_{l=1}^{k} x_{i_l} = \sum_{l=1}^{k} (f(\{1, 2, \cdots, i_l\}) - f(\{1, 2, \cdots, i_l - 1\})).
$$

Using the definition of $\rho$-submodularity, we obtain

$$
f(\{1, 2, \cdots, i_l\}) - f(\{1, 2, \cdots, i_l - 1\}) \leq \rho^{-1}(f(\{i_1, i_2, \cdots, i_l\}) - f(\{i_1, i_2, \cdots, i_{l-1}\})).
$$
Therefore,
\[
\sum_{j \in S} x_j = \sum_{l=1}^{k} x_{i_l}
\]
\[
\leq \sum_{l=1}^{k} \rho^{-1} \left( f(\{i_1, i_2, \ldots, i_l\}) - f(\{i_1, i_2, \ldots, i_{l-1}\}) \right)
\]
\[
= \rho^{-1} f(S).
\]

This shows that \( x \in \text{CORE}_{\rho^{-1}}(f) \).

**Appendix G. Core of the Minimum-Cost Matching Problem**

Consider the LP relaxation of the minimum cost perfect matching problem on the weighted complete bipartite graph \( G(U, V, E, w) \), where the variable \( x_{ij}, (i, j) \in E \) denotes the extent to which vertex \( i \) is matched with vertex \( j \). It is well-known that the relaxed LP is Totally Unimodular and has an integral optimal solution (Schrijver, 1998). The value of the minimum cost matching \( f([N]) \) for the entire bipartite graph is given by the optimal value of the following LP.

\[
\begin{align*}
\min \sum_{(i,j) \in E} w_{ij} x_{ij} \\
\text{s.t.} \\
\sum_{j: (i,j) \in E} x_{ij} &\geq 1, \quad \forall i \in U \\
\sum_{i: (i,j) \in E} x_{ij} &\geq 1, \quad \forall j \in V \\
x_{ij} &\geq 0, \quad \forall (i, j) \in E.
\end{align*}
\]

Associating a dual variable \( u_i \) to the constraint (32) and a dual variable \( v_j \) to the constraint (33) for all \( i \in U, j \in V \), we can write down the dual of LP (31) as follows:

\[
\begin{align*}
\max \sum_{i \in U} u_i + \sum_{j \in V} v_j \\
\text{s.t.} \quad u_i + v_j &\leq w_{ij}, \quad \forall (i, j) \in E \\
u_i &\geq 0, \quad \forall i \in U \\
v_j &\geq 0, \quad \forall j \in V.
\end{align*}
\]

Let \((u^*, v^*)\) be an optimal solution to the dual LP, which can be efficiently obtained using the Hungarian algorithm (Kuhn, 1955). Define the components of a vector \( g \) as follows:

\[
g_k = \begin{cases} 
    u^*_k, & \text{if } k \in U \\
    v^*_k, & \text{if } k \in V.
\end{cases}
\]
We now show that the vector $g \in \text{CORE}_1(f)$. Since both the primal and dual LPs are feasible, strong duality implies that

$$f([N]) = \sum_{i \in U} u_i + \sum_{j \in V} v_j = \sum_{i \in U \cup V} g_i. \quad (38)$$

On the other hand, consider any perfect matching $M$ on the nodes $S_U \cup S_V$. From the dual feasibility of $(u^*, v^*)$ and using the dual constraint (35), we have

$$\sum_{(i,j) \in M} w_{ij} \geq \sum_{i \in S_U} u_i^* + \sum_{j \in S_V} v_j^*. \quad (39)$$

Taking minimum over all perfect matchings $M$ on $S \equiv S_U \cup S_V$, we have

$$\sum_{i \in S} g_i \leq f(S). \quad (39)$$

Equations (38) and (39), taken together, shows that $g \in \text{CORE}_1(f)$. Interestingly, from the dual feasibility (36) and (37), it also follows that the vector $g$ is component-wise non-negative. Furthermore, from Proposition 4, it follows that $||g||_2 \leq N w_{\max}/\sqrt{2}$.

**Appendix H. Constructing an admissible vector when $f$ contains an $m$-dictator**

We begin with the following definition.

**Definition 16 ($m$-dictator set)** For some $m > 0$, let $D^m_f \subseteq [N]$ be the set of elements such that for any set $S$, if $S \cap D^m_f \neq \emptyset$ then $f(S) \geq m$. Then, we call $D^m_f$ as the $m$-dictator set associated with the set function $f$.

**Proposition 17** Assume that the reward function $f$ is monotone non-decreasing and normalized i.e., $S \subseteq T \implies f(S) \leq f(T)$, and $f(\emptyset) = 0$. Define $M \equiv f([N])$. Hence, $0 \leq f(S) \leq M, \forall S \subseteq [N]$. Suppose $f$ has a non-empty $m$-dictator set $D^m_f$ associated with it.

1. Let the set of vectors $\mathcal{G}(D^m_f, [N])$ be defined as follows:

   $$\mathcal{G}(D^m_f, [N]) = \left\{ x \in \mathbb{R}^N_{\geq 0} : x_i = 0, \forall i \notin D^m_f, \text{ and } \sum_{i \in D^m_f} x_i = M \right\}$$

   Then, $\mathcal{G}(D^m_f, [N]) \subseteq \text{CORE}_{M/m}(f)$. In particular, the vector $g$ defined as $g_i = M 1(i = i^*), i \in [N]$ is $M/m$-admissible, where $i^* \in [N]$ is an $m$-dictator.

2. $f$ is $\frac{M}{m}$-admissible.

**Proof** Observe that if (1) of Proposition 17 holds true, (2) follows immediately by definition. Let $g \in \mathcal{G}(D^m_f, [N])$. For any subset $S \subseteq [N]$,

$$\sum_{i \in S} g_i = \sum_{i \in S \cap D^m_f} g_i + \sum_{i \in S \setminus D^m_f} g_i = \sum_{i \in S \cap D^m_f} g_i,$$
where the last equality holds by definition of $G(D_f^m, [N])$. If $S \cap D_f^m = \emptyset$,

$$\sum_{i \in S} g_i = 0 \leq \frac{M}{m} f(S)$$

as $f(S) \geq 0$. Suppose, $S \cap D_f^m \neq \emptyset$,

$$\sum_{i \in S} g_i = \sum_{i \in S \cap D_f^m} g_i \leq M \leq \frac{M}{m} f(S)$$

where (a) holds because $g \geq 0$ and $\sum_{i \in D_f^m} g_i = M$ and (b) holds by the definition of the $m$-dictator set. So,

$$\sum_{i \in [N]} g_i = \sum_{i \in D_f^m} g_i = M = f([N]).$$

As $g$ satisfies the conditions in Definition 2, $G(D_f^m, [N]) \subseteq \text{CORE}_{M/m}(f)$.

Remarks: We would like emphasize that the construction of the admissible vector $g$ in Proposition 17 is not exhaustive in general. Consider a simple three-player game among the players $\{1, 2, 3\}$ with the reward function defined as follows:

$$f(S) = \begin{cases} 1, & \text{if } 1 \in S \text{ or } 2 \in S, \\ 0, & \text{otherwise} \end{cases}$$

For $m = 1$ and given $f$, $M = 1$ and $D_f^m = \{1, 2\}$. So, $g = (t, 1 - t, 0), t \in [0, 1]$ lies in the 1-core. It is easy to verify that $g$ satisfies all the conditions mentioned in Definition 2. The set of $2^3 - 1 = 7$ constraints associated with any vector $g$ in the core of this reward function is listed below:

$$g_1 \leq 1$$
$$g_2 \leq 1$$
$$g_3 \leq 0$$
$$g_1 + g_2 \leq 1$$
$$g_2 + g_3 \leq 1$$
$$g_1 + g_3 \leq 1$$
$$g_1 + g_2 + g_3 = 1.$$

The set of all solutions for the above set of constraints can be verified to be $g' = (t, 1 - t, 0)$ for $t \in [0, 1]$. Now, consider the above three player game with a modified reward function:

$$f(S) = \begin{cases} 2, & \text{if } 1 \in S \\ 1, & \text{if } 1 \notin S \text{ but } 2 \in S \\ 0, & \text{otherwise}. \end{cases}$$

For $m = 1$ and given $f$, $M = 2$ and $D_f^m = \{1, 2\}$. Note that $g = (3, 0, -1)$ lies in $\text{CORE}_2(f)$ but $g \notin G(D_f^m, [N])$. 

27
Appendix I. Proof of the existence of a $\sigma_{\min}(X)/4d$-dictator for the SPARSE LINEAR REGRESSION PROBLEM

From Altschuler et al. (2016, Lemma 2), we have that for any two subsets of columns $S$ and $T$ with $f(S) \geq f(T)$, there exists a column $v^* \in S$ such that

$$f(T \cup v^*) - f(T) \geq \sigma_{\min}(X_S) \frac{(f(S) - f(T))^2}{4|S|f(S)}.$$  \hfill (40)

We use the above bound with $S = [d]$ and $T = \emptyset$. The facts that $X$ is full rank and $||y||_2 = 1$, imply that $f([d]) = 1$. Since $f(\emptyset) = 0$, we obtain the following bound from (40):

$$f(\{v^*\}) \geq \frac{\sigma_{\min}(X)}{4d}.$$  \hfill (40)

Since the reward function $f(\cdot)$ is monotone, the above inequality proves the result.

Appendix J. Online Subset Selection under Semi-Bandit Feedback

In this section, we extend the online subset selection policy for linear rewards, given in Algorithm 1, to the semi-bandit feedback model. Recall that in the semi-bandit model, the learner receives the components of the reward vector, $g_t(i)$, only for the elements $i \in S_t$ in the subset selected by the learner on round $t$. As before, the learner’s objective is to attain a sublinear expected regret defined in Theorem 1. Here, the expectation is taken over all internal randomizations of the algorithm.

In Algorithm 5, we propose a simple extension of Algorithm 1, where we use the inverse propensity scoring (step 5 in Algorithm 5) to estimate the unobserved coordinates. Note that no explicit exploration term is included in Algorithm 5. In the following, we analyze the static regret bound achieved by this policy.

**Algorithm 5** Online Subset Selection Policy with LINEAR-REWARDS (Semi-bandit feedback)

**Require:** Sequence of linear reward functions $\{f_t\}_{t \geq 1}$ with coefficients $\{g_t\}_{t \geq 1}$, $\eta > 0$.

1: $p \leftarrow (\frac{k}{N}, \frac{k}{N}, \ldots, \frac{k}{N})$.
2: for every round $t$: do
3: Sample a $k$-set according to the inclusion probability vector $p$ using Madow’s algorithm.
4: Receive the reward components of the coefficient vector $g_t$ on the selected subset $\{g_{t,i}, \forall i \in S_t\}$.
5: Set $\hat{g}_{t,i} \leftarrow \frac{g_{t,i}}{p_{t,i}}$ for $i \in S_t$ and 0 otherwise. \hfill // Inverse propensity scores
6: Feed the estimated vector $\hat{g}_t$ and update the inclusion probability vector $p$ according to the FTRL($\eta$) update (4).
7: end for

**Analysis:** Note that, by definition, the estimated components of the reward vectors are unbiased as

$$\mathbb{E}[^{\hat{g}}_{t,i}] = \sum_{S:i \in S} q_t(S) \frac{g_{t,i}}{p_{t,i}} = \frac{g_{t,i}}{p_{t,i}} \sum_{S:i \in S} q_t(S) = g_{t,i},$$

28
where $q_t(S)$ is the (conditional) probability of choosing the $k$-set $S$. The last equality holds as $p_{t,i} = \sum_{i \in S} q_t(S)$. Thus we have that $\mathbb{E}[(\hat{g}_t, p)] = \langle \hat{g}_t, p \rangle$ for any vector $p$.

Now recall the following standard static regret bound for the FTRL($\eta$) policy from Hazan (2019, Theorem 5.2). For a bounded, convex and closed set $\Omega$ and a strongly convex regularization function $R : \Omega \rightarrow \mathbb{R}$, consider the standard FTRL updates, i.e.,

$$x_{t+1} = \arg\max_{x \in \Omega} \left[ \left( \sum_{s=1}^{t} \nabla^2 g_s \right)x - \frac{1}{\eta} R(x), \right]$$

(41)

where $\nabla_s = \nabla f_t(x_s), \forall s$. Taking $\Omega \equiv \Delta^N_k$ to be the capped-simplex defined by (2) and (3) and $R(x) \equiv \sum_{i=1}^{N} x_i \ln x_i$ to be the entropic regularizer, the regret of the FTRL($\eta$) policy can be upper-bounded as follows:

$$\text{Regret}^{\text{FTRL}} \leq 2\eta \sum_{t=1}^{T} ||\nabla_t||_{s,t}^2 + \frac{R(u) - R(x_1)}{\eta},$$

(42)

where the quantity $||\nabla_t||_{s,t}^2$ denotes the square of the dual norm of the vector induced by the Hessian of the regularizer evaluated at some point $x_{t+1/2}$ lying in the line segment connecting the points $x_t$ and $x_{t+1}$. Hence, for the LINEAR-REWARD problem with the sequence of reward vectors $\hat{g}_1, \ldots, \hat{g}_T$, we have:

$$\max_{p^* \in \Delta^N_k} \sum_{t \leq T} \langle \hat{g}_t, p^* \rangle - \sum_{t \leq T} \langle \hat{g}_t, p_t \rangle \leq 2\eta \sum_{t=1}^{T} ||\nabla_t||_{s,t}^2 + \frac{R(u) - R(x_1)}{\eta},$$

The following diagonal matrix gives the Hessian of the entropic regularizer:

$$\nabla^2 R(p_{t+1/2}) = \text{diag}([p_{1}^{-1}, p_{2}^{-1}, \ldots, p_{N}^{-1}]) \implies ||\nabla_t||_{s,t}^2 = \langle p_t, \hat{g}_t^2 \rangle,$$

In the above, the vector $\hat{g}_t^2$ is obtained by squaring each component of the vector $\hat{g}_t$. To bound the second term in (42), define a probability distribution $\tilde{p} = p/k$. We have

$$0 \geq R(p) = \sum_{i} p_i \ln p_i = -k \sum_{i} \tilde{p}_i \ln \frac{1}{\tilde{p}_i} \quad (\text{Jensen's inequality}) \geq -k \ln \sum_{i} \tilde{p}_i = -k \ln \frac{N}{k}.$$

Hence, for this problem, the general regret bound in (42) simplifies to the following:

$$\max_{p^* \in \Delta^N_k} \sum_{t \leq T} \langle \hat{g}_t, p^* \rangle - \sum_{t \leq T} \langle \hat{g}_t, p_t \rangle \leq \frac{k}{\eta} \ln \frac{N}{k} + 2\eta \sum_{t=1}^{T} \langle p_t, \hat{g}_t^2 \rangle.$$

Taking expectations of both sides with respect to the random choice of the policy and using Jensen’s inequality, we have

$$\max_{p^* \in \Delta^N_k} \sum_{t \leq T} \mathbb{E} \left[ \langle \hat{g}_t, p^* \rangle \right] - \sum_{t \leq T} \langle \hat{g}_t, p_t \rangle \leq \frac{k}{\eta} \ln \frac{N}{k} + 2\eta \sum_{t=1}^{T} \mathbb{E} \left[ \langle p_t, \hat{g}_t^2 \rangle \right],$$

(43)
where (a) holds because \( \sum_{i \in S} q_t(S) = p_{t,i} \), and by definition \( ||g_t||^2 \leq G^2 \). Combining results from (43) and (44), we have:

\[
\max_{p^* \in \Delta_k^N} \sum_{t \leq T} \langle g_t, p^* \rangle - \sum_{t \leq T} \langle g_t, p_t \rangle \leq \frac{k \ln N}{k} + 2\eta G^2 T \tag{45}
\]

Setting \( \eta = \sqrt{\frac{k \ln(N/k)}{2G^2 T}} \), we get the following static regret bound

\[
\max_{p^* \in \Delta_k^N} \sum_{t \leq T} \langle g_t, p^* \rangle - \sum_{t \leq T} \langle g_t, p_t \rangle \leq 2G \sqrt{2kT \ln \frac{N}{k}},
\]

where \( G \) is a uniform upper bound to the \( \ell_2 \) norms of the reward vectors \( \{g_t, t \geq 1\} \).

**Regret bound for learning non-linear reward functions under semi-bandit feedback**

Observe that in the complete information setting, The \textsc{Sc}ore policy, described in Algorithm 2, uses only the reward vector \( g_t \) and not the entire set function \( f_t \). We use a feedback model similar to Takemori et al. (2020), where marginal gains for the items chosen in set \( S_t \) are observed when the reward functions are submodular. Consequently, we define the subset selection problem for \( \alpha \)-admissible functions in the semi-bandit setting as follows: at any round \( t \), the learner plays a \( k \)-set \( S_t \), and the adversary reveals the selected reward components \( \{g_{t,i}, i \in S_t\} \) for some \( g_t \in \text{CORE}_\alpha(f_t) \). Then, we use Algorithm 5 to construct an unbiased estimator \( \hat{g}_t \) and subsequently update the weights. Finally, the same augmented regret bound given in (8) follows immediately in the semi-bandit setting using the inequalities (10) and (11) and the semi-bandit regret bound in (45). From Proposition 4, for \( \alpha \)-admissible reward functions taking values in \([0, M]\), we can take \( G \equiv \alpha M \sqrt{T} \). It is easy to see that the space and time complexity of the semi-bandit version is of the same order as in the complete information setting.
