In this paper we explore the incommensurate spatial modulation of spin-spin correlations as the intrinsic property of the doped Mott insulator, described by the $t-J$ model. We show that such an incommensurability is a direct manifestation of the phase string effect introduced by doped holes in both one- and two-dimensional cases. The magnetic incommensurate peaks of dynamic spin susceptibility in momentum space are in agreement with the neutron-scattering measurement of cuprate superconductors in both position and doping dependence. In particular, this incommensurate structure can naturally reconcile the neutron-scattering and NMR experiments of cuprates.

I. INTRODUCTION

Antiferromagnetic (AF) spin correlations in cuprates persist into metallic phase as evidenced, for example, in neutron-scattering measurements. Compared to insulating phase, however, a qualitative change in the nature of AF correlations has also been observed. The original magnetic peak in dynamic spin susceptibility centered at momentum $(\pi, \pi)$ splits into four incommensurate peaks at $(\pi \pm \pi \delta, \pi)$ and $(\pi, \pi \mp \pi \delta)$ in metallic or superconducting regime, as has been found in the LSCO compounds (a recent measurement indicates the similar structure for YBCO compounds as well). The incommensurability is insensitive to both energy and temperature, corresponding to a new spatial modulation of spin-spin correlations in real space.

The incommensurability $\delta$ has been identified to be proportional to doping concentration $\delta$ in approximately a universal fashion: $\delta \approx 2\delta$. This observation poses a critical challenge to theories of incommensurability based on the Fermi-surface topology since the Fermi-surface encloses a $1-\delta$ amount of electrons according to the Luttinger theorem, it is not a trivial issue why the doping concentration $\delta$ of holes should dictate the incommensurability. A very similar issue has already been well known in the transport properties of cuprates where charge carriers are always characterized by hole-nature with the total number determined by $\delta$ despite a large Fermi surface. This phenomenon has been interpreted due to the existence of a doped-Mott-insulator because of the strong Coulomb interaction among electrons. With striking similarity, magnetic incommensurability may be another intrinsic consequence of the doped-Mott-insulator.

A further challenge to any theory of magnetic incommensurability comes from NMR spin relaxation rates, $1/T_1$. As pointed out by Walstedt, Shastry, and Cheong if the non-Korringa behavior of $1/T_1$ for planar $^{63}Cu$ nuclear spins — a hallmark of normal-state anomalies of cuprates — originates from the AF correlations, this effect may generally ‘leak’ to the planar $^{17}O$ nuclear spins if the AF correlations become incommensurate. Thus the non-Korringa behavior would have to show up in the temperature dependence of $1/T_1$. This was indeed predicted by theories where the incommensurability is interpreted in terms of the Fermi-surface topology. But experimentally the ‘leakage’ of non-Korringa behavior to $^{17}O$ spins has never been observed and the temperature behavior of $1/T_1$ is drastically different from that of $1/T_1$, implying a near-perfect commensurate AF correlations within a one-component-theory framework. So how to reconcile the NMR and neutron measurements remains to be a serious puzzle in constructing a consistent microscopic theory.

In this paper, we present a theoretical understanding of spatially modulated spin-spin correlations as a result of the doped Mott insulator described by the $t-J$ model. Such a Mott insulator at half-filling is an antiferromagnet whose magnetic properties have been well understood. A hole doped into such a antiferromagnet will induce a phase string ‘defect’ in the spin background which is nonrepairable at low-energy. It represents a singular doping effect and profoundly modifies both spin and charge correlations in the presence of finite density of doped holes. At low-doping where the ‘rigidity’ of the half-filled AF state still persists, described by a bosonic resonating valence bond (RVB) pairing, a mean-field theory incorporating the phase string effect is able to combine the AF insulating phase, superconducting phase, and an anomalous normal state within a unified phase diagram naturally. In the present paper we demonstrate that it is in this regime a spatial modulation of spin-spin correlations indeed occurs as a direct manifestation of the nonrepairable phase string effect. Such an incommensurability is consistent with the experimental measurements in cuprate superconductors. In particular, such a mechanism for spatial modulation can uniquely reconcile the above-mentioned neutron and NMR experiments in cuprates.
The present work will be based on the so-called phase string formalism of the $t-J$ model in which the phase string effect is explicitly incorporated into the Hamiltonian. In this formalism, spin raising operator $S^+_i$ reads

$$S^+_i = b^+_i b_i (-1)^i e^{i\Phi^h_i}. \tag{1.1}$$

Here $b^+_i$ denotes a bosonic spinon annihilation operator. Compared to the conventional Schwinger-boson formalism, a distinctive feature is the phase $\Phi^h_i$ which is defined by

$$\Phi^h_i \equiv \sum_{l \neq i} \text{Im} \ln \left( z_i - z_l \right) n^h_l. \tag{1.2}$$

It describes a phase vortex structure centered on holons: $n^h_l$ is the holon number operator at site $l$ and $z_i = x_i + i y_i$ represents the complex coordinate of a lattice site $i$. If one changes $z_i$ continuously around a holon site $l$ once, $\Phi^h_i$ will gain an additional $2\pi$ phase. Such a vorticity around a holon reflects the topology of the phase string effect as schematically illustrated in Fig. 1. In this way, spins become nonlocally dependent on the positions of holes and the doping effect explicitly enters spin-spin correlations through $\Phi^h_i$, in addition to a modification of spinon spectrum via the Hamiltonian.

In Sec. II, we show that an incommensurate spatial oscillation because of $\Phi^h_i$ will modulate the original commensurate oscillation of $(-1)^i$ in (1.1) at finite doping in both one-dimensional (1D) and two-dimensional (2D) cases. The incommensurability in 1D recovers the well-known Luttinger liquid behavior, while in 2D it explains the experimental results in cuprates including the incommensurate peak positions in momentum space and the doping dependence of the incommensurability. We then further show that the effect of such a spatial modulation of spin-spin correlations cannot be picked up by NMR spin relaxation rates precisely due to its singular nature associated with doped holes, and thus reconcile the neutron and NMR experiments in cuprates. Finally, a conclusive discussion is presented in Sec. III.

**II. INCOMMENSURABILITY DUE TO PHASE-STRING EFFECT**

According to (1.1), the transverse spin-spin correlation function can be written down as follows

$$\langle S^+_i(t) S^-_j(0) \rangle = (-1)^{i-j} \langle b^+_i(t) b^+_j(t) \Pi^h_{ij} b^+_j(0) b^+_i(0) \rangle, \tag{2.1}$$

where

$$\Pi^h_{ij} (t) \equiv e^{i\Phi^h_{ij}(t)} e^{-i\Phi^h_{ij}(0)}. \tag{2.2}$$

(The longitudinal correlation function will be discussed in the Appendix.) At half-filling, $\Phi^h_i = 0$ and the prefactor $(-1)^{i-j}$ in (2.1) determines a commensurate AF oscillation of the spin-spin correlation function: $(-1)^{i-j} \equiv e^{iQ_0 \cdot (r_i - r_j)}$ with the AF wavevector

$$Q_0 = (\pm \pi/a, \pm \pi/a), \tag{2.3}$$

where $a$ is the lattice constant. [Note that the average in (2.1) will also produce a (small) term which oscillates as $(-1)^{i-j}$ in real space and compensates the prefactor in (2.1), leading to a ferromagnetic component of spin-spin correlations at half-filling.]

At finite doping, the topological phase $\Phi^h_i$ defined in (1.2) will qualitatively modify the spatial modulation of the AF spin-spin correlations. For the purpose of illustration, in the following we discuss the 1D case first as an example, where the phase string effect has been already shown to play a crucial role responsible for Luttinger liquid behavior. Then we discuss the 2D case and make comparison with experiment.

**A. Incommensurability in 1D**

In 1D case, $\Phi^h_i$ simply reduces to

$$\Phi^h_i = \pm \pi \sum_{l>i} n^h_l. \tag{2.4}$$
Let us consider the equal-time case first, where

\[ \Pi_{ij}^h = e^{i(\Phi_i^h - \Phi_j^h)} = e^{i \pi \sum_{l < i < j} n_l^h}. \]  

(2.5)

Here we assume \( i < j \) without loss of generality.

Expression (2.5) clearly shows that every holon sitting between \( i \) and \( j \) will contribute a \( \pi \) phase shift to \( \Pi_{ij}^h \). Due to the spin-charge separation in 1D, one may take separate averages over spinon and holon in (2.4). Define \( N_{ij}^h = \sum_{l < i < j} n_l^h \). The average of \( \Pi_{ij}^h \) over holon degrees of freedom can be evaluated as follows

\[ \langle \Pi_{ij}^h \rangle = e^{i \pi (N_{ij}^h)} \left( e^{i \pi (N_{ij}^h - \langle N_{ij}^h \rangle)} \right) = e^{i \delta Q(x_i - x_j)} \times \text{slow oscillation part}, \]  

(2.6)

with

\[ \delta Q(x_i - x_j) \equiv \pm \pi (N_{ij}^h). \]  

(2.7)

To leading approximation, \( \Pi_{ij}^h \) will then contribute to an additional oscillation factor at wavevector

\[ \delta Q = \pm \pi \delta/a. \]  

(2.8)

Besides such a singular oscillating part there is a slow oscillation part in (2.6) which only gives rise to an additional decay, determined at \( J \to 0^+ \) limit as

\[ \langle \Pi_{ij}^h \rangle \sim 1/|x_{ij}|^{1/2} \]  

(2.9)

at long-distance limit (\( v_c \) is the Fermi velocity of holon) without modifying the incommensurate position at \( 2k_f \). The correct power-law decay of the spin-spin correlation function at \( J/t \to 0^+ \) limit is given by:

\[ \langle S^+(t)S^- (0) \rangle \sim \frac{\cos(2k_f x_{ij})}{(x_{ij}^2 - v_c^2 t^2)^{1/4}}, \]  

(2.10)

where \( v_c \) is the spinon velocity. Furthermore, the similar phase-string effect also gives rise to a Luttinger-liquid type Fermi-surface singularity in the momentum distribution of electrons at \( k_f \) with an exponent 1/8. Even though the \( 2k_f \) incommensurate structure in spin-spin correlations is still connected to the Fermi-momentum \( k_f \) here, a Fermi-liquid type interpretation in terms of the Kohn anomaly is no longer accurate since the electron quasiparticle description is not elementary anymore. A correct picture is that each holon as a topological object carries a spin domain-wall with it so that in calculating the large-distance spin-spin correlation function one has to count how many holons in between each of them contributes a \( \pi \) phase-shift as shown in (2.3).

B. Incommensurate structure in 2D

The spin-charge separation in 2D is slightly different from 1D. While in 1D spinons and holons can be treated as decoupled at low-energy and long-wave length limit, spinons and holons in 2D, though they still belong to independent degrees of freedom, will influence each other through some topological gauge fields even in long-distance limit. For example, spinons are subjected to a lattice gauge field \( A_{lm}^h \neq 0 \) in 2D in the Hamiltonian [\( \hat{A}_{lm} \) refers to a nearest-neighbor link]. As a physical quantity, the spin-charge separation function defined in (2.1) should be gauge-invariant, independent of the gauge choice of \( A_{lm}^h \). This requires \( \Pi_{ij}^h \) to be able to absorb the gauge phase arising from the spinon propagator under a gauge transformation: \( A_{lm}^h \to A_{lm}^h + (\theta_l - \theta_m) \) and \( b_{l\sigma} \to b_{l\sigma} e^{i \sigma \theta_l} \) which leaves the Hamiltonian unchanged.

In fact, \( \Pi_{ij}^h \) itself can be expressed in terms of a gauge field. Introduce the following relation

\[ \text{Im } \ln (z_i - z_l) - \text{Im } \ln (z_j - z_l) = \int_G d\mathbf{r} \cdot \hat{z} \times (\mathbf{r} - \mathbf{r}_l) / |\mathbf{r} - \mathbf{r}_l|, \]  

(2.11)
where Γ is an arbitrary path connecting i and j without crossing the site l. In the following we always choose Γ as one of the shortest-paths between i and j without crossing any lattice site. Then $\Pi_{ij}^h$ at $t = 0$ can be expressed as

$$\Pi_{ij}^h = e^{i(\phi_i^h - \phi_j^h)} = e^{i/2 \int_r \hat{A}^h(r)}, \quad (2.12)$$

where

$$\hat{A}^h(r) = \frac{1}{2} \sum_l (n_l^h \hat{z} \times (r - r_l)) / |r - r_l|^2. \quad (2.13)$$

Similarly the lattice gauge field $A_{lm}^h$ in the Hamiltonian can be also expressed by such a vector potential $\hat{A}^h(r)$ as follows

$$A_{lm}^h = \int_l^m dr \cdot \hat{A}^h(r). \quad (2.14)$$

Then it is straightforward to verify the gauge invariance of the spin-spin correlation function defined in (2.1).

In the mean-field theory, the gauge field $A_{lm}^h$ defined at a nearest-neighbor link is treated by smearing the holon number distribution locally. It is equivalent to replacing $\hat{A}^h(r)$ in (2.14) by its continuum version $\hat{A}^h(r)$ defined by

$$\hat{A}^h(r) = \frac{1}{2} \int d^2 r' \rho^h(r') \hat{z} \times (r - r') / |r - r'|^2, \quad (2.15)$$

where the holon density $\rho^h(r')$ is obtained by smearing the holon-number distribution on lattice site, $n_l^h$, in the continuum space at a scale of $a$. However, if one naively does the same replacement in $\Pi_{ij}^h$ for a larger spatial separation of i and j, an important effect similar to the singular phase string effect discussed in 1D would be lost.

Generally one may define

$$\Delta \phi_T \equiv 2 \int_\Gamma dr \cdot [\hat{A}^h(r) - A^h(r)], \quad (2.16)$$

and rewrite

$$\Pi_{ij}^h = e^{i/2 \int_r \hat{A}^h(r) + i \Delta \phi_T}. \quad (2.17)$$

$\Delta \phi_T$ will then keep track of the aforementioned singular effect in passing from $\hat{A}^h(r)$ to $A^h(r)$.

According to (2.11), the contribution to $2 \int_\Gamma dr \cdot \hat{A}^h(r)$ from a holon sitting at site l is given by the angle spanned between two straight lines connecting l−i and l−j as shown in Fig. 2a. The r.h.s. of (2.11) is a continuous function of $r_1$ as long as $r_1$ stays away from the path Γ connecting i and j. So when l is shifted at a scale of a in the limit of $|r_1 - r_j| \gg a$, the change of the corresponding angle is negligibly small. In this case, taking a continuum limit by neglecting the underlying lattice can be justified. But if $r_1$ crosses the branch-cut Γ, then it is easy to see that the angle defined in (2.11) has a 2π jump. Fig. 2a shows a nearest-neighbor lattice link that is across the path Γ and the value of (2.11) changes from $\sim \pi$ to $-\pi$, namely, by $\sim 2\pi$ for the two lattice sites of the link. It is important to note that in $\Pi_{ij}^h$ such a 2π change has no effect and thus a holon sitting at either lattice site of the nearest-neighbor link across Γ has approximately the same contribution to $\Pi_{ij}^h$ by a phase shift $\pi$. On the other hand, $A^h(r)$ is obtained by taking a continuum limit with holon distribution being ‘coarse-grained’ at scale of a, and in $2 \int_r dr \cdot \hat{A}^h(r)$ the contribution from those holons near the path Γ within the lattice scale of a will be simply cancelled out due to the opposite signs across Γ as shown in Fig. 2a. Thus, we find

$$e^{i/2 \int_r \hat{A}^h(r)} \simeq e^{i/2 \int_r \hat{A}^h(r) + i \Delta \phi_T} \simeq e^{i/2 \int_r \hat{A}^h(r) + i \Delta \phi_T}, \quad (2.18)$$

where $N_h(\Gamma)$ denotes the total number of holons at those nearest-neighbor links across the path Γ shown in Fig. 2b.

So the nonlocal phase shift in 2D is identified by

$$\Delta \phi_T \simeq \pm \pi N_h(\Gamma). \quad (2.19)$$

As shown in Fig. 2b, the path Γ is always ‘covered’ by nearest-neighbor lattice links along the $\hat{y}$ axis if $|x_i - x_j| \geq |y_i - y_j|$. Noting that each site the average holon number is $\delta$, one has
Similarly, the path $\Gamma$ in Fig. 2b can be covered by nearest-neighbor lattice links along $\hat{x}$ axis if $|x_i - x_j| \leq |y_i - y_j|$, and the effective holon number along the path $\Gamma$ is estimated to be $2\delta|y_i - y_j|/a$. Thus, two kinds of oscillations in real space are combined to give

$$
\langle N_h(\Gamma) \rangle \sim 2\delta \frac{|x_i - x_j|}{a}.
$$

(2.20)

The singular phase string effect is thus retained in the phase factor $e^{i\Delta \phi_{\Gamma}}$ and the gauge-invariant quantity inside $\langle \ldots \rangle$ on the r.h.s. can be now evaluated by the mean-field approximation. In obtaining (2.22) we have made approximations by neglecting the fluctuations in $\Delta \phi_{\Gamma}$ itself as well as the temporal dependence of $\Pi_{ij}^0(t)$. These effects in 1D lead to an additional decay of the spin-spin correlation function in spatial and temporal space but do not change the incommensurate momentum position. We expect the same thing to happen in 2D where these effects merely cause some extra broadening of magnetic peaks. These broadening effects should become minimal at low-temperature when a Bose condensation of holons occurs, which corresponds to a superconducting condensation in (the phase string theory both spinon and holon are bosonic).

Therefore, similar to 1D, the spatial oscillation factor $e^{i\Delta \phi_{\Gamma}}$ in (2.22) will lead to incommensurate momentum shifts from $Q_0$ by $\delta Q = (\pm \pi/a, 0)$ and $(0, \pm \pi/a)$ according to (2.22). It is noted that $\theta_{ij}^x$ in (2.21) will modify the plane-wave oscillation function but will not change the peak positions at $\delta Q$. The incommensurability $\delta = 2\delta$ obtained here is in agreement with the experiments discussed in the beginning. Of course, whether such an incommensurate structure can become observable also depends on the broadening effect introduced by the spinon propagator [the average on the r.h.s. of (2.22)]. With the singular phase string effect being explicitly sorted out, such a gauge-invariant quantity can be directly calculated in terms of the mean-field theory developed in Ref. [13]. For the sake of compactness, the detailed mathematical manipulation is given in the Appendix.

We compute the momentum-dependence of the dynamic spin susceptibility function corresponding to those two cases with the same parameters. Fig. 3 shows $\chi''(q, \omega)$ as the Fourier transformation of $\chi''(i, j; \omega)$ given in the Appendix. The momentum scan is illustrated by the left top insert in Fig. 3 which is along $q_y = \pi/a$, and four full circles denote the incommensurate peak positions at $Q_0 + \delta Q$. First of all, the dashed curve corresponds to aforementioned uniform-phase case at $\omega = 2E_s$. It shows no explicit incommensurate peak splitting because the average in (2.23) contributes to a large broadening in momentum space which smears the peak structure composed of four incommensurate peaks. The corresponding resonance-like peak around $\omega = 2E_s$ in the insert of Fig. 3 was used to explain the 41 meV peak in the optimally doped $YBa_2Cu_3O_7$ compound. A single it broad AF peak shown in Fig. 3 is also consistent with the neutron-scattering experiments in such a compound.

The incommensurate peaks at $Q_0 + \delta Q$ explicitly show up in the solid curve (inhomogeneous phase) in Fig. 3 at small $\omega$. Since there is a spinon Bose condensation in this case, the susceptibility function has nonzero weight persists over to low energy until $\omega = 0$ (the insert of Fig. 3). In this case, the spin-spin correlation length at small
\(\omega\) becomes much longer than the uniform-phase case such that the underlying incommensurate structure becomes visible. Experimentally, the incommensurate splitting has been indeed observed at small energy transfer in \(\text{LSCO}\) compounds \[^4\] at the same positions and with the same doping-dependent incommensurability \(\delta\) shown in Fig. 3. Most recently, a similar incommensurate structure has been also identified in the underdoped \(\text{YBCO}\) compounds \[^4\].

C. Reconciliation of the incommensurability with NMR measurements

The NMR experiment has served as an another powerful tool in probing the magnetic properties in cuprates. A combination of NMR and neutron-scattering measurements should provide a more complete picture for the nature of AF spin-spin correlations in these materials.

The NMR spin-lattice relaxation rate for nuclear spins at planar \(^{17}\text{O}\) sites, \(1/\tau_{1}\), can be expressed in terms of the real-space spin-spin correlations as follows \[^{17}\]–\[^{19}\]:

\[
\frac{1}{\tau_{1}} \approx \frac{T}{N} \sum_{i} \left[ G_{ii} + \frac{1}{4} \sum_{j=nn(i)} G_{ij} \right] \tag{2.23}
\]

where

\[
G_{ij} = \chi''(i,j,\omega) \bigg|_{\omega\to0^+}. \tag{2.24}
\]

According to (2.23), \(1/T_{1}\) only involves real-space spin-spin correlations up to nearest-neighboring sites. The spin relaxation rate for planar \(^{63}\text{Cu}\) nuclear spin can be similarly obtained \[^{17}\]–\[^{19}\], which involves spin-spin correlations up to next-nearest-neighboring sites. So in the one-component theory \[^{17}\]–\[^{19}\] of the NMR in cuprates, only short-distance spin-spin correlations are relevant.

It has been well known \[^{17}\]–\[^{19}\] that a sharp commensurate AF component in \(\chi''(i,j)\) will have strong cancellation between the on-site and nearest-neighboring-site terms in (2.23) due to the staggered factor \((-1)^{i-j}\). So commensurate AF correlations, which presumably are responsible to a so-called non-Korringa temperature behavior in \(1/\tau_{1}\), will have much less significant contribution to \(1/T_{1}\), as has been discussed by many authors \[^{17}\]–\[^{19}\] and this is consistent with experimental measurements where \(1/\tau_{1}\) shows a much weaker and quite different behavior usually attributed to the non-AF correlations in \(\chi''\).

However, the neutron-scattering measurements indicate AF correlations in cuprates should be \textit{incommensurate} in nature as discussed in the previous section. Once the sharp commensurate AF component is replaced by an incommensurate AF structure experimentally, it was pointed out \[^{17}\]–\[^{19}\] that the non-Korringa behavior of \(1/T_{1}\) at \(^{63}\text{Cu}\) would usually ‘leak’ to the \(1/\tau_{1}\) sites, causing a temperature behavior in \(1/T_{1}\) which is not consistent with experimental results. This is due to an imperfect cancellation of the AF component of \(\chi''\) in (2.23) after the change from a sharp commensurate to an incommensurate (or a more broadened) magnetic structure around \(\text{Q}_{0}\). Indeed, various theories \[^{17}\]–\[^{19}\] based on the Fermi surface topology in which the incommensurability arises from the Kohn anomaly have predicted a \textit{similar} non-Korringa behavior for \(1/T_{1}\), in contrast to the experimental results. In this sense, incommensurate AF correlations seem inconsistent with the NMR data. In order to resolve this issue, some authors \[^{17}\]–\[^{19}\] even have proposed to modify the form of hyperfine coupling as an alternative way out.

But such a paradox can be easily reconciled in the phase string description without changing the hyperfine interactions which are determined based on the local chemical structure of cuprates and are consistent with the Knight shift data \[^{17}\]–\[^{19}\]. In the present theory, the incommensurate structure or spatial modulation, as represented by \(e^{i\Delta_{r}q}\) in (2.22), has been directly attributed to the phase vortex structure whose singular centers are bound to holons. The resulting incommensurate oscillation in spin-spin correlation function is only meaningful at a scale much larger than the size of the singular center. As for a nearest-neighbor lattice link \((ij)\), \(\Pi_{ij}^{h}\) will simply reduce to

\[
\Pi_{ij}^{h} = e^{i\Phi_{ij}^{h}} e^{-i\Phi_{ij}^{h}} = e^{iA_{ij}^{h}}, \tag{2.25}
\]

where \(A_{ij}^{h}\) is the lattice gauge field given in (2.14). In the mean-field approximation \(A_{ij}^{h}\) is replaced by \(\int dr \cdot A^{h}(r)\) as discussed before, without causing any additional singular phase shift, namely, \(\Delta \Phi_{r} = 0\). It is because there can be no holon sitting between two nearest-neighboring spins. Trivially, one also has \(\Pi_{ii}^{h} = 1\). Thus, \(1/\tau_{1}\) in (2.23) will simply not be able to ‘see’ any incommensurate phase shift, even though such a incommensurate spatial modulation does exist in large-distance correlations as given by (2.21). The latter can be picked up by the neutron-scattering measurement as discussed in previous section.
Recall that the phase string effect leads to a vortex phase. Incommensurability is a unique property of metallic phase, which should disappear in the localized regime. Here are in accord with the typical experimental data of cuprates. $1/63T_1T$ exhibits a non-Korringa $1/T$ behavior at high temperature while $1/17T_1T$ remains roughly a constant (Korringa behavior). Note that the decrease of the relaxation rates at low-$T$ is due to the spin gap $\sim E_\sigma$, which also decides the superconducting transition temperature $T_c$ around the same scale $\delta$. One thing we need to emphasize here is that even though in the uniform-phase case the momentum structure in Fig. 3 looks like a commensurate peak, it actually is composed of four incommensurate peaks with stronger broadening, and thus the ‘leakage’ effect would be expected even stronger in this case. In fact, if we assume the incommensurate spatial modulation $2\Phi$ to persist into short-distance $\sim a$, the non-Korringa temperature dependence will then immediately show up in $1/17T_1$ precisely as pointed out in Ref. 10. Therefore, the origin of the incommensurability from the nonlocal vortex structure of (2.2), i.e., the phase string effect, is indeed crucial to resolve this issue.

### III. DISCUSSIONS

In the present paper, we have related the magnetic incommensurability to the intrinsic properties of the doped Mott insulator. In the Mott insulator, the spins are the only degrees of freedom not frozen by the strong on-site Coulomb interaction. Holes doped into such a Mott insulator always introduce a phase frustration (phase string effect) on the spin background by violating the Marshall sign rule. Such a phase string effect then contributes a unique spatial modulation to the spin-spin correlations as demonstrated in this paper, which is more or less independent of energy and temperature but linearly depends on the doping concentration. In momentum space it leads to an explicit incommensurate splitting of the AF peak in the dynamic spin susceptibility when the spin correlation length is sufficiently long, in agreement with the neutron-scattering measurements of cuprates in both the peak positions and doping dependence. Furthermore, due to the phase string origin of this incommensurability, it has been shown that the NMR spin relaxation rates should not be able to pick up the incommensurability AF correlations at length scales comparable to the lattice constant, and thus conflicting implications of neutron and NMR data can be reconciled within the present framework. Conversely, one may also conclude that the magnetic incommensurability observed in cuprate superconductors provides a direct experimental evidence for the phase string effect in the doped Mott insulator.

We conclude this paper by making several remarks on some related issues. First of all, we point out that the present magnetic incommensurability is a unique property of metallic phase, which should disappear in the localized regime. Recall that the phase string effect leads to a vortex phase $e^{i\Phi_i}$ emerging in spin operator $\Phi_i$ which is the reason for the incommensurate spatial modulation. It has been previously discussed that the same phase $e^{i\Phi_i}$ also causes the disappearance of the AF long range order. It was argued that only in the hole-localized regime (insulating phase) where the phase string effect is no longer effective, the phase $e^{i\Phi_i}$ can be compensated by the vortex phase carried by spinons which become vortices in the insulating phase, and the AF long range order may be recovered. By the same token, the incommensurability induced by $e^{i\Phi_i}$ should be also gone in this localized regime at small doping. This is in accord with the experiments where only a commensurate AF peak has been observed in the insulating phase.

Secondly, as briefly mentioned in Sec. II A, even though $2k_F$ incommensurate oscillation of 1D spin-spin correlation function may be viewed as the Kohn anomaly of the Fermi surface effect, it is not very meaningful because single electron excitations are no longer elementary and the spin-spin correlation function cannot be reasonably approximated by a ‘bubble’ diagram composed of the single-electron Green’s function without including high order corrections. Similarly the 2D magnetic incommensurability in the phase string formalism does not necessarily exclude the relevance of the Fermi surface topology. Instead it implies that the latter explanation is no longer accurate as holon and spinon become new elementary excitations. Especially, the interpretation of the doping-dependent incommensurability and the reconciliation of neutron and NMR measurements can only be naturally realized in this phase string description of the doped-Mott-insulator.

Finally, we emphasize that the incommensurability discussed in the present paper is due to the topology associated with each individual holon. It has nothing directly to do with the phase separation or charge inhomogeneity at a larger length scale involving many holes as discussed in literature (like the stripe phase), including the inhomogeneous (underdoping) metallic regime studied within the phase string formalism. Nevertheless, there is still a fundamental connection: all of these may be attributed to the competition between the kinetic energy of holes and superexchange energy of spins and the resulting tendency towards phase separation. The vorticity surrounding each holon may be regarded as a microscopic version of phase separation against a uniform spiral phase.

Welch foundation, and the State of Texas through the Texas Center for Superconductivity at University of Houston.

APPENDIX: DYNAMIC SPIN SUSCEPTIBILITY FUNCTION

1. Mean-Field Theory

The $t - J$ model in the phase string formalism can be written in two terms in the mean-field approximation: $H_s + H_h$. $H_s$ governs the spinon degrees of freedom and $H_h$ determines the holon degrees of freedom. In the present paper, we mainly focus on the spin magnetic properties decided by $H_s$:

$$H_s = \sum_{m\sigma} E_m \gamma^\dagger_{m\sigma} \gamma_{m\sigma} + \text{constant}, \quad (A1)$$

where $\gamma^\dagger_{m\sigma}$ is the creation operator of bosonic spinon elementary excitations. The spinon excitation spectrum $E_m$ in this mean-field theory is given by

$$E_m = \sqrt{\lambda^2_m - \xi^2_m}, \quad (A2)$$

in which, $\lambda_m$ is defined by

$$\lambda_m = \lambda - \alpha |\xi_m|, \quad (A3)$$

where $\lambda$ is the Lagrangian multiplier to be determined by the condition of total spin number equal to $N(1 - \delta)$ ($N$ is the total number of lattice sites.) The coefficient $\alpha$ is a ratio of two energy scales: $\alpha = J_h/J_s$, in which $J_h = \delta t'$ describes an effective hopping effect on spinon degrees of freedom with $t' \sim J$ and $J_s = (J/2)\Delta^s$ with $\Delta^s$ being the bosonic RVB order parameter characterizing the present mean-field state. The Lagrangian multiplier $\lambda$ and the RVB order parameter $\Delta^s$ are determined by the following mean-field equations, respectively,

$$2 - \delta = \frac{1}{N} \sum_m \frac{\lambda_m}{E_m} \coth \frac{\beta E_m}{2}, \quad (A4)$$

and

$$\Delta^s = \frac{1}{4N} \sum_m \frac{\xi^2_m}{J_s E_m} \coth \frac{\beta E_m}{2}. \quad (A5)$$

The spectrum $\xi_m$ will be modified by doping effect through a gauge field $A^h_{ij}$ as the eigenvalue of the following equation:

$$\xi_m w_{m\sigma}(i) = -J_s \sum_{j = nn(i)} e^{i \sigma A^h_{ij}} w_{m\sigma}(j). \quad (A6)$$

Here $A^h_{ij}$ (with $j = nn(i)$) is originally defined by the following gauge invariant condition

$$\sum_C A^h_{ij} = \pi N^h_C, \quad (A7)$$

where $C$ is an arbitrary counterclockwise closed path and $N^h_C$ is the number of holes enclosed by it. In the present mean-field theory, the dynamic effect of $A^h_{ij}$ is replaced by a randomness as it comes from an independent degrees of freedom (holons). $N^h_C$ may be rewritten as $\tilde{N}^h_C + \delta N^h_C$ with fluctuating $\delta N^h_C$. Correspondingly $A^h_{ij}$ describes a uniform fictitious magnetic field with a random flux fluctuation on the top of it. Two kinds of mean-field solutions due to
different strengths of the fluctuations are found which are distinguished by whether there is a Bose condensation of spinons or not at low temperature. The former case is called inhomogeneous metallic phase and the latter is called uniform metallic phase in Ref. 17.

Finally, the Bogoliubov transformation relates $\gamma$-operator to the spinon operator $b_{i\sigma}$ is given as follows:

$$b_{i\sigma} = \sum_m \left( u_m \gamma_{m\sigma} - v_m \gamma_{m-\sigma}^\dagger \right) e^{i\sigma x_m} w_{m\sigma}(i),$$

where $u_m = 1/\sqrt{2}(\lambda_m/E_m + 1)^{1/2}$ and $u_m = 1/\sqrt{2}(\lambda_m/E_m - 1)^{1/2} \text{sgn}(\xi_m)$. The phase factor $e^{i\sigma x_m}$ is determined up to a change

$$e^{i\sigma x_m} \rightarrow -\text{sgn}(\xi_m) \times e^{i\sigma x_m}$$

each time when a holon changes sublattices.

### 2. Dynamic spin susceptibility

Let us first consider the transverse component defined in Matsubara representation as follows

$$\chi_{+-}(i; j; i\omega_n) = \int_0^\beta d\tau e^{i\omega_n \tau} \langle T_\tau S_i^+ (\tau) S_j^-(0) \rangle.$$  

(A10)

Here $\omega_n = \frac{2\pi n}{\beta}$ and

$$\langle T_\tau S_i^+ (\tau) S_j^-(0) \rangle = (-1)^{i-j} \left( T_\tau b_{i\uparrow}^\dagger (\tau) b_{i\downarrow} (\tau) \Pi_{\downarrow j} (\tau) b_{j\uparrow}^\dagger (0) b_j (0) \right).$$  

(A11)

According to discussions in Sec. IIB, the r.h.s. of (A11) can be expressed by

$$(-1)^{i-j} \left( T_\tau b_{i\uparrow}^\dagger (\tau) b_{i\downarrow} (\tau) \Pi_{\downarrow j} (\tau) b_{j\uparrow}^\dagger (0) b_j (0) \right)e^{2\int_\tau^\beta d\phi \Delta \phi}.$$  

(A12)

In the mean-field approximation one has

$$\langle T_\tau b_{i\uparrow}^\dagger (\tau) b_{i\downarrow} (\tau) \Pi_{\downarrow j} (\tau) b_{j\uparrow}^\dagger (0) b_j (0) \rangle_s = \langle T_\tau b_{i\uparrow}^\dagger (\tau) b_{j\uparrow}^\dagger (0) b_j (0) \rangle_s \langle T_\tau b_{i\downarrow} (\tau) b_j (0) \rangle_s + \langle T_\tau b_{i\uparrow}^\dagger (\tau) b_j (0) \rangle_s \langle T_\tau b_{i\downarrow} (\tau) b_{j\uparrow}^\dagger (0) \rangle_s,$$  

(A13)

where $\langle \ldots \rangle_s$ denotes the average over the spinon degrees of freedom. According to the mean-field theory outlined in the above section, one has

$$b_{i\sigma}^\dagger (\tau) = e^{H_{\tau} b_{i\sigma}^\dagger} e^{-H_{\tau}} = \sum_m \left( u_m \gamma_{m\sigma} e^{E_m \tau} - v_m \gamma_{m-\sigma} e^{-E_m \tau} \right) w_{m\sigma}^* (i) e^{-i\sigma x_m}.$$  

(A14)

Then by noting $w_{m-\sigma}^* = w_{m\sigma}$ one finds

$$\langle T_\tau b_{i\sigma}^\dagger (\tau) b_{j-\sigma} (0) \rangle_s = -\sum_m u_m v_m \langle w_{m\sigma}^* (i) w_{m\sigma} (j) \rangle e^{-i\sigma \Delta x_m} \left( e^{E_m \tau} \langle \gamma_{m\sigma}^\dagger \gamma_{m\sigma} \rangle_s + e^{-E_m \tau} \langle \gamma_{m-\sigma}^\dagger \gamma_{m-\sigma} \rangle_s \right),$$  

(A15)

at $\tau > 0$ where $e^{-i\sigma \Delta x_m}$ is introduced to incorporate the phase shift effect. $e^{-i\sigma \Delta x_m}$ may be determined based on how many exchanges between the spinon and background holons. The spinon will acquire a phase shift $\pm \pi$ for $\xi_m > 0$ due to $-\text{sgn}(\xi_m) = -1$ each time it exchanges positions with a holon. Thus, if $N_{ij}^h$ denotes the number of holons encountered and exchanged with the involved spinon on the shortest-path $\Gamma$ connecting $i$ and $j$, the total phase shift acquired by the spinon at $\xi_m > 0$ is $\pm \pi N_{ij}^h \simeq \Delta \phi \Gamma$. Then we may write down
\[ e^{-i\sigma\Delta\chi_{m}} = \begin{cases} 1, & \text{if } \xi_{m} < 0 \\ (-1)^{N_{0}^{m}}, & \text{if } \xi_{m} > 0 \end{cases} \]  
(A16)

It is noted that for each \( m \) with \( \xi_{m} < 0 \), one always can find a state \( \bar{m} \) with \( \xi_{\bar{m}} = -\xi_{m} > 0 \) with a wavefunction

\[ w_{\bar{m}\sigma}(i) = (-1)^{i}w_{m\sigma}(i) \]  
(A17)

according to (A6). Then in terms of (A16) and (A17) we finally have (at \( \tau > 0 \))

\[ \left< T_{\tau}b_{\sigma}^{\dagger}(\tau)b_{\sigma}(-\tau) \right> = \left( (-1)^{i-j+N_{0}^{m}} - 1 \right) \times \sum_{m}u_{m}v_{m}(w_{m\sigma}^{*}(i)w_{m\sigma}(j)) [n(E_{m})e^{E_{m}\tau} + (1 + n(E_{m}))e^{-E_{m}\tau}] , \]  
(A18)

where the summation \( \sum_{m} \) only runs over those states with \( \xi_{m} < 0 \). Similarly, one can also determine

\[ \left< T_{\tau}b_{\sigma}^{\dagger}(\tau)b_{\sigma}(-\tau) \right> = \left( (-1)^{i-j+N_{0}^{m}} + 1 \right) \sum_{m}(w_{m\sigma}^{*}(i)w_{m\sigma}(j)) \times [u_{m}^{2}n(E_{m})e^{E_{m}\tau} + v_{m}^{2}(1 + n(E_{m}))e^{-E_{m}\tau}] , \]  
(A19)

as well as other averages in (A13).

Then after integrate out \( \tau \) in (A10) and identify \( (-1)^{N_{0}^{m}} \) with \( e^{i\Delta\phi_{r}} \) in operator form, one obtains

\[ \chi_{+-}(i, j; i\omega_{n}) \approx \chi_{+-}^{(+)}(i, j; i\omega_{n}) + (-1)^{i-j}e^{i\Delta\phi_{r}} \cdot \chi_{+-}^{(+)}(i, j; i\omega_{n}) , \]  
(A20)

where

\[ \chi_{+-}^{(+)}(i, j; i\omega_{n}) = \sum_{mm'}K_{mm'}^{+-}(i, j) \left[ (p_{mm'}^{\pm})^{2}n(E_{m'}) - n(E_{m}) \right] \frac{1}{i\omega_{n} + E_{m} - E_{m'}} \]  
\[ \times \left( 1 + n(E_{m}) + n(E_{m'}) \right) \frac{1}{2} \frac{1}{i\omega_{n} + E_{m} + E_{m'} - \frac{1}{i\omega_{n} - E_{m} - E_{m'}}} \]  
(A21)

with

\[ K_{mm'}^{+-}(i, j) = 2 \left[ e^{i\int_{r}dr\cdot A_{\sigma}^{\pm}w_{m\sigma}(i)w_{m\sigma}(j)} \right] \left[ e^{i\int_{r}dr\cdot A_{\sigma}^{\pm}w_{m\sigma}(i)w_{m\sigma}(j)} \right] \]  
\[ = \sum_{\sigma} \left[ e^{i\sigma\int_{r}dr\cdot A_{\sigma}^{\pm}w_{m\sigma}(i)w_{m\sigma}(j)} \right] \left[ e^{i\sigma\int_{r}dr\cdot A_{\sigma}^{\pm}w_{m\sigma}(i)w_{m\sigma}(j)} \right] . \]  
(A22)

In obtaining the last line, the symmetry \( w_{m\sigma}^{*} = w_{m\sigma}^{*} \) has been used. The coherent factors, \( p_{mm'}^{\pm} \) and \( l_{mm'}^{\pm} \) are defined by

\[ p_{mm'}^{\pm} = u_{m}u_{m'} \pm v_{m}v_{m'}, \]  
\[ l_{mm'}^{\pm} = u_{m}v_{m'} \pm v_{m}u_{m'} . \]  
(A23)

Finally, the dynamic spin susceptibility function \( \chi_{+-}^{''}(i, j; i\omega) \) can be obtained as the imaginary part of \( \chi_{+-}^{'} \) after an analytic continuation \( i\omega_{n} \rightarrow \omega + i0^{+} \) is made:

\[ \chi_{+-}^{''}(i, j; \omega) = \Phi_{+-}^{(-)}(i, j; \omega) + (-1)^{i-j}e^{i\Delta\phi_{r}} \cdot \Phi_{+-}^{(+)}(i, j; \omega) , \]  
(A24)

where

\[ \Phi_{+-}^{(\pm)}(i, j; \omega) = \frac{\pi}{2} \sum_{mm'}K_{mm'}^{+-}(i, j) \left[ (1 + n(E_{m}) + n(E_{m'})) \left( l_{mm'}^{\pm} \right)^{2} \text{sgn}(\omega) \right] \cdot \delta(|\omega| - E_{m} - E_{m'}) + 2 \left( n(E_{m}) - n(E_{m'}) \right) (p_{mm'}^{\pm})^{2} \delta(\omega + E_{m} - E_{m'}) . \]  
(A25)

The longitudinal spin susceptibility function can be similarly obtained:

10
The phase factors $e^{\pm i\alpha}$ are introduced to explicitly show the gauge invariance of $K_{m'm'}^z$. Generally, one expects the gauge-invariant quantity $e^{i\alpha} K_{m'm'}^z$ to be independent of $\sigma$ or to be real, which in turn means $K_{m'm'}^z = K_{m'm'}^+$. Consequently, the rotational invariance of spin-spin correlations is retained. The corresponding dynamic spin susceptibility function is given by

$$\chi''_{zz}(i, j; \omega) = \Phi_{zz}^-(i, j; \omega) + (-1)^{i-j} e^{i\Delta\phi} \Phi_{zz}^+(i, j; \omega),$$

(A29)

where

$$\Phi_{zz}^\pm (i, j; \omega) = \frac{n}{2} \sum_{m'm'}^\prime K_{m'm'}^z(i, j) \left[ (1 + n(E_m) + n(E_{m'})) (l_{m'm'}^\pm)^2 \text{sgn} \omega \right] \delta(|\omega| - E_m - E_{m'}) + 2 (n(E_m) - n(E_{m'})) (p_{m'm'}^\pm)^2 \delta(\omega + E_m - E_{m'}) \right].$$

(A30)

Fig. 1 The topology of a holon due to the phase string: any closed loop around it will cut through the phase string once or an odd number of times.

Fig. 2a The illustration of the angle defined by (2.11) at site $l$. Such an angle jumps approximately $2\pi$ at a nearest-neighbor lattice link (bold one) across the path $\Gamma$ connecting sites $i$ and $j$ in the limit $|r_i - r_j| \gg a$.

Fig. 2b The path $\Gamma$ connecting $i$ and $j$ is covered by the nearest-neighbor links along the $\hat{y}$-axis (bold links) in the case that $|x_i - x_j| \geq |y_i - y_j|$.

Fig. 3 Dynamic spin susceptibility function $\chi''(q_x, \omega)$ versus $q_x$ (with a fixed $q_y$ at $\pi/a$) at $\delta = 0.143$. Two cases: the dashed curve corresponds to the uniform phase at $\omega = 2E_s \sim 0.4J$ where $\chi''_L(\omega)$ is peaked (the insert); the solid curve corresponds to the inhomogeneous phase at $\omega \sim 0$. The $\omega$-dependence of $\chi''_L(\omega)$ in the insert is from Ref. 17. The positions of the incommensurability is illustrated by four full circles at the left top. Note that the maxima of $\chi''$ in two cases are scaled to the same value for comparison.

Fig. 4 The contrast of the non-Korringa and Korringa behavior of the NMR spin relaxation rates for planar copper and oxygen nuclear spins for the uniform phase case at $\delta = 0.143$.
